Financial Conditions, r^*, and the Transmission of Monetary Policy Surprises

Draft for discussion

11 November 2026

Abstract

Monetary policy is the main tool for stabilizing the economy, but estimates of its effects have been unreliable. In samples that start in the mid-1990s, standard methods applied to surprises around Federal Reserve announcements give unemployment that falls after a tightening and prices that do not respond. I keep the surprises and change how their effects are traced through the economy. I measure how the two-year yield and a broad financial conditions index move in the half hour around each announcement, and carry those moves forward in a daily and a monthly model. Both are measured relative to the neutral rate. Traced through the two-year yield alone, the surprises give the familiar wrong signs. Traced through the index relative to the neutral rate, a tightening raises unemployment and lowers the price level, and the ratio of the price response to the unemployment response is of conventional size. The main results hold across alternative samples, measures of the neutral rate, trends, credit conditions and surprises.

1 Introduction

Monetary policy is the main tool for stabilizing the economy. Its use rests on estimates of how much a change in policy moves unemployment and inflation. In samples that start after the early 1980s, standard methods often give a surprise tightening small effects on unemployment, or effects of the wrong sign (Ramey, 2016). Two concerns follow. One is that policy has become less powerful (Boivin and Giannoni, 2006; Boivin et al., 2010). The other is that inflation responds little to slack, so that lowering inflation requires a large and lasting rise in unemployment (Hazell et al., 2022; Del Negro et al., 2020). I ask whether these findings reflect how policy works or how its effects are measured.

The question matters in practice. From 2022 to 2023 the Federal Reserve raised its policy rate by more than 5 percentage points. Policymakers expected costs: in August 2022 the Chair warned of "some softening of labor market conditions" and called these "the unfortunate costs of reducing inflation" (Powell, 2022). They also described policy as working through broad financial conditions: in November 2023 the Chair noted that "Financial conditions have tightened significantly in recent months, driven by higher longer-term bond yields, among other factors" (Powell, 2023). The standard tools for measuring the effects of policy leave those conditions out.

The answer is that measurement matters. I use the policy-news surprise of Nakamura and Steinsson (2018) around 252 FOMC announcements from 1996 to 2026, and I change only how its effects are traced through the economy. Traced through the two-year yield alone, the surprises give the result of the standard methods: unemployment falls after a tightening, by 0.95 percentage point after a year in a recursive VAR and 0.91 in a proxy VAR, and prices do not respond. Traced through a broad financial conditions index, with the index and the yield both measured relative to the neutral rate r^*, a policy move that raises the two-year yield 1 percentage point raises unemployment by

0.50 percentage point after two years and lowers the core price level by 0.81 percent. Lowering the price level 1 percent costs about 0.9 percentage-point years of unemployment, a conventional sacrifice ratio. These responses have the signs that theory predicts, where the standard methods give the wrong ones. In the terms of Barnichon and Mesters (2021), the ratio of the price response to the unemployment response is −0.90 after three years, against about −0.15 for 1990–2008 in their estimates.

The approach has three features.

First, I measure the effect of each surprise in the announcement window, the half hour around the announcement, in which unemployment and inflation cannot move. A daily model then traces how the two-year yield and financial conditions evolve after each announcement, and monthly unemployment and core inflation respond to their monthly averages, as in a standard vector autoregression (VAR). As in Jacobson et al. (2026), the model takes into account when each announcement falls within its month.

Second, financial conditions enter as a whole (Boivin et al., 2010). The financial conditions index (FCI) combines the 10-year yield, equity valuation and the real dollar, weighted by their responses to policy news. A policy surprise raises the FCI about 1 unit per percentage point on the two-year yield. An ordinary monthly rise of 1 percentage point in the two-year yield comes with a rise of only 0.36 to 0.51 unit. A model with the yield alone therefore traces the ordinary move in the yield, which carries much less of the change in financial conditions than a policy surprise does.

Finally, I measure the yield and the index relative to r^*, the rate that neither speeds up nor slows down the economy. The neutral rate fell from the 1990s to the 2010s (Laubach and Williams, 2003; Holston et al., 2017, 2023; Hamilton et al., 2016; Kiley, 2020b), and interest rates trended down with it while activity trended up, so a model that links the level of rates to activity partly picks up these opposite trends. Inflation depends on how long real rates stay above or below r^*, so the adjustment should matter most for prices. The FCI and the order of steps (nominal, real, then relative to r^*) come from a companion note on financial conditions and were fixed before this analysis (FCI note, 2026).

Earlier fixes improve the surprise or the timing of the outcome. I leave both alone and change the channel: policy reaches the economy through long rates, stock prices and the dollar, and these have to be measured relative to r^*. The main results hold across alternative samples, measures of r^*, trends, credit conditions and surprises (Section 4).

1.1 Connection to the literature

Surprises and their effects. Interest-rate surprises around Federal Reserve announcements were meant to settle the measurement problem. The FOMC makes its decision before the announcement, so market moves in a narrow window around it, at most about 100 minutes long, cannot have caused the decision. The change in interest-rate futures and Treasury yields in that window is news about policy, or at least about the part of policy that moves interest rates (Kuttner, 2001; Gürkaynak et al., 2005). These surprises measure the effects of policy on asset prices precisely (Bernanke and Kuttner, 2005; Hanson and Stein, 2015; Nakamura and Steinsson, 2018; Swanson, 2021). When they are used to measure effects on unemployment and inflation, the old puzzles often return. Recent work offers four explanations, each with a fix. First, an announcement reveals the Fed's view of the economy as well as its policy, so a surprise tightening can signal good news (Romer and Romer, 2000; Nakamura and Steinsson, 2018), and separating the two gives larger price effects (Jarociński and Karadi, 2020; Miranda-Agrippino and Ricco, 2021). Second, part of each surprise can be predicted from earlier public data, and removing it, and adding surprises from the Chair's speeches, gives larger and more precise effects (Bauer and Swanson, 2023a,b). Third, markets react

within minutes but unemployment and inflation are monthly averages, and measuring inflation daily removes most of the wrong-signed response (Jacobson et al., 2026). Fourth, credit costs carry part of the effect (Gertler and Karadi, 2015; Caldara and Herbst, 2019), and announcements move stock prices and the dollar much more than interest-rate surprises can explain, so that treated as a separate shock this news has large effects (Kroencke et al., 2021; Bauer et al., 2023; Boehm and Kroner, 2024; Bauer et al., 2026; Boehm et al., 2026). Most of this work traces the surprise forward through a single interest rate in nominal terms.

Identifying the effects of policy. My paper is closest in spirit to Jacobson et al. (2026). Like them, I hold the surprise and the method fixed and change one measurement. They change how often the outcome is measured; I change how the channel from policy to the economy is measured. They study inflation only, while my main result is for activity. Both changes remove wrong-signed responses, and both point to a mismatch between what the economist measures and what drives decisions. Bauer and Swanson (2023a) and Jarociński and Karadi (2020) improve the surprise itself. In my design a surprise enters only through its immediate effect on the two-year yield and the FCI, and through its timing. Their fixes and mine can in principle be combined. My approach also changes which assumptions the estimates rest on. It depends less on how strongly the surprise moves rates over a month, and less on its link to earlier news. It relies instead on the assumption that the economy responds to a given change in financial conditions in the same way, whatever caused it.

The use of futures-based surprises in monthly models goes back to Faust et al. (2004). The choice of surprise series can matter (Bu et al., 2021; Brennan et al., 2025), and so can the number of lags (Coibion, 2012). Related work on timing and mixed frequencies includes Kilian (2024), Chudik and Georgiadis (2022), Francis et al. (2011), Ghysels (2016) and Gazzani and Vicondoa (2020).

Financial channels and risk appetite. Gertler and Karadi (2015) and Caldara and Herbst (2019) are closest in emphasizing financial channels. I use a broad index and measure it relative to r^*, but leave credit spreads out of the baseline. Recent studies of risk appetite and the "non-yield" shock, the announcement news that moves stocks and the dollar beyond what interest rates explain, differ from mine in where they place risk premia (Bauer et al., 2026; Boehm and Kroner, 2024; Boehm et al., 2026). They treat policy-driven moves in risk premia as a second shock; I treat them as part of financial conditions. The channels are the same in both views: stock prices, the dollar and credit costs. My estimates keep only the part of the stock and dollar moves that comes with interest-rate news, so they measure the effects of that dimension of policy, not of all policy news. The response of stock prices to policy-driven moves in long rates has also changed over time (Kiley, 2014). Caballero et al. (2026) propose a neutral level of the FCI itself, FCI*, because r^* must otherwise absorb asset-price movements that the index already captures. I keep r^* for the rates inside the two-year yield and the index; using gaps to FCI* is a natural extension.

The power of policy and the Phillips curve. A long literature finds that the effects of policy shocks became smaller after the early 1980s. It attributes the change to a more systematic response of policy and to better-anchored expectations (Boivin and Giannoni, 2006; Boivin et al., 2010; Primiceri, 2005). Others argue that standard identification fails after the late 1980s because policy became more forward-looking (Barakchian and Crowe, 2013).

On the Phillips curve, recent work finds a small slope (Hazell et al., 2022; Del Negro et al., 2020; Ball and Mazumder, 2019; Fitzgerald et al., 2024). It also stresses that the slope is hard to identify when policy offsets demand shocks (McLeay and Tenreyro, 2020), and that conventional methods tend to understate it (Barnichon and Mesters, 2020). Policy shocks offer one way to identify it. Barnichon and Mesters (2021) measure the tradeoff by the ratio of cumulative inflation to cumulative unemployment after such shocks. In that metric they find a much flatter tradeoff after 1990 than before. Responses to policy shocks also map directly into the outcomes of alternative policies

(McKay and Wolf, 2023). I add evidence of this kind and show that the measured tradeoff depends on how the stance of policy is measured. My price result relies on 2020–22, when inflation surged and then began to fall. Others read that episode as evidence of a steeper, nonlinear Phillips curve (Benigno and Eggertsson, 2023), or as the unwinding of supply shocks (Bernanke and Blanchard, 2025).

2 Empirical approach

The model has three pieces. A surprise moves the two-year yield and the FCI by amounts measured in the announcement window: the vector b in equation (13). A daily VAR, equation (14), carries those two series forward. Their monthly averages then enter a monthly VAR for unemployment and inflation, equation (15). Appendix D gives the construction of the series, the algorithm for tracing responses and the bootstrap, and Appendix E lists the data.

2.1 Measuring financial conditions

The FCI is the market index of FCI note (2026): a weighted sum of the 10-year Treasury yield, stock valuations and the real broad dollar. Indexes of this kind are weighted sums of financial variables (Hatzius et al., 2010). They differ mainly in where the weights come from. FCI-G takes them from large macroeconomic models (Ajello et al., 2023). Mine come from the event-study regressions long used to measure how asset prices respond to policy (Kuttner, 2001; Bernanke and Kuttner, 2005; Hanson and Stein, 2015; Nakamura and Steinsson, 2018).

Policy news. Let ΔX_a be the 5×1 vector of changes in the current- and next-meeting federal funds futures and the second to fourth eurodollar futures in the window around announcement a. Following Nakamura and Steinsson (2018), let p_a be the first principal component of these changes, signed so that it moves with the fourth eurodollar future. Policy news is p_a rescaled so that one unit moves the two-year yield y^2 by 1 percentage point:

$$s_a = \gamma\, p_a, \qquad \gamma = \frac{\sum_a p_a\, \Delta y_a^2}{\sum_a p_a^2}. \tag{1}$$

Weights. Let ΔA_a be the vector of changes in the 10-year yield, the S&P 500 and the DXY dollar index in the announcement window. The companion note treats these changes as

$$\Delta A_a = \psi\, s_a + \eta_a, \tag{2}$$

where ψ holds the policy responses and η_a is other news, with covariance matrix Σ. It estimates ψ by regressing each element of ΔA_a on s_a and a constant, and Σ from the residuals, over 253 announcements from January 1996 to September 2026. The weights are those that recover the policy component most precisely (one-factor generalized least squares):

$$w = \frac{\Sigma^{-1}\psi}{\psi'\Sigma^{-1}\psi}. \tag{3}$$

Because $w'\psi = 1$ and s_a is scaled to the two-year yield, a policy move that raises the two-year yield 1 percentage point raises the index by 1 unit. The weights are 0.61 on the 10-year yield, -0.051 per percent on stock valuations and 0.065 per percent on the dollar. Each of the three accounts for about a third of the index's response to policy.

Three versions. In month t, the index in version v is

$$F_t^v = w_B\, B_t^v + w_Q\, Q_t^v + w_D\, D_t, \tag{4}$$

measured as a deviation from its sample mean. Here D_t is 100 times the log of the real broad dollar in every version. With y_t^{10} the 10-year yield, π_t^{10} 10-year expected inflation, and $(E/P)_t$ the inverse of the cyclically adjusted price-earnings ratio (CAPE), the other two terms are:

$$\text{Nominal:} \quad B_t = y_t^{10}, \qquad Q_t = 100 \ln \text{CAPE}_t, \tag{5}$$

$$\text{Real:} \quad B_t = y_t^{10} - \pi_t^{10}, \qquad Q_t = 100 \ln \text{CAPE}_t, \tag{6}$$

$$r^*\text{-gap (baseline):} \quad B_t = y_t^{10} - \pi_t^{10} - r_t^*, \qquad Q_t = -\frac{100}{\overline{E/P}} \left[(E/P)_t - r_t^* \right]. \tag{7}$$

In the r^*-gap version, stocks are measured by the gap between their earnings yield and r^*. The term $100/\overline{E/P}$, with $\overline{E/P}$ the sample average, converts this gap to the units of the log CAPE, so that the weight on stocks is the same in every version. CAPE is a real valuation measure, so stocks do not change between the nominal and real versions. For r^* I use the New York Fed's current Laubach–Williams estimates (Holston et al., 2023). These "one-sided" estimates use only data up to each date, with the model's parameters estimated on the full sample.

The two-year yield. The two-year yield is adjusted in the same steps. With y_t^2 the nominal yield and π_t^2 two-year expected inflation (from the Cleveland Fed; Haubrich et al., 2012),

$$R_t^{\text{nominal}} = y_t^2, \qquad R_t^{\text{real}} = y_t^2 - \pi_t^2, \qquad R_t^{r^*\text{-gap}} = y_t^2 - \pi_t^2 - r_t^*. \tag{8}$$

Expected inflation and r^* are monthly or quarterly and move slowly. The daily series add their interpolated monthly values to daily market prices, so day-to-day moves come from markets (Appendix D).

2.2 Why financial conditions and r^*

Policy reaches spending and prices through many interest rates, asset prices and the dollar. A standard VAR with one interest rate can miss most of that route, and the omission can produce the puzzles.

2.2.1 The standard transmission mechanism

Monetary policy sets the short-term interest rate today and, through its communications, shapes what people expect that rate to be in the future. Few households and businesses borrow at the policy rate. They face the rates on consumer credit, mortgages and business debt, which arbitrage links to current and expected short-term rates. The same rise in rates raises the return investors require on stocks. For businesses, a higher cost of capital raises the user cost of new equipment and buildings, and investment falls (Jorgenson, 1963; Hall and Jorgenson, 1967). The value of existing capital relative to its replacement cost falls as well (Tobin, 1969). For households, lower stock prices lower wealth, and consumption depends on wealth as well as on current income (Ando and Modigliani, 1963; Friedman, 1957). Higher rates also strengthen the dollar, which shifts spending toward imports and reduces exports (Fleming, 1962; Mundell, 1963).

Interest rates of many maturities, equity prices and the dollar therefore form the core of the transmission mechanism (Boivin et al., 2010). These links run from the early work cited above to modern models of the business cycle, in closed and open economies (Christiano et al., 2005; Smets and Wouters, 2007; Galí and Monacelli, 2005). Models with heterogeneous households give more weight to the indirect effects that work through income (Kaplan et al., 2018; Auclert, 2019). But in all of these models the short-term rate matters mainly because of what it does to the prices and rates that people actually face. And they act with a lag (Friedman, 1961).

What matters in these models is not the nominal rate but the real rate relative to the neutral rate r^*. The same holds for the other parts of financial conditions: a given yield or stock valuation is tighter when r^* is low than when it is high. The distinction matters most for inflation. Spending responds to financial conditions within months. Inflation responds to the slack that builds up over time, so it depends on how long, and by how much, conditions stay tight relative to r^*. A measure of conditions that ignores a falling r^* will overstate how tight policy has been, and by more the longer the period. That error is largest for the cumulative effects that drive inflation.

2.2.2 What standard VARs leave out

The workhorse evidence on monetary policy comes from VARs with a few macroeconomic variables and one interest rate (Bernanke and Blinder, 1992; Christiano et al., 1999). Some studies add a credit spread (Gertler and Karadi, 2015; Caldara and Herbst, 2019), and factor models bring in many more series (Bernanke et al., 2005). But long-term yields, equity valuations and the dollar are usually absent from the small models used to measure the effects of policy, although some recent work adds the dollar and stock-market volatility (Boehm et al., 2026). These are the variables that, on the mechanism above, carry those effects. Concern about missing variables is not new: Sims (1992) argued that the price puzzle arises because the Federal Reserve responds to information that small VARs do not contain (see also Castelnuovo and Surico, 2010). My concern is different. Here the missing variables are the channel itself.

A simple model shows what this omission can do. Let U_t be the unemployment gap, i_t the policy rate and f_t financial conditions, with a higher f_t meaning tighter conditions:

$$U_t = \rho_U \, U_{t-1} + \kappa \, f_{t-1} + \varepsilon_t^U, \tag{9}$$

$$f_t = \rho_f \, f_{t-1} + \lambda \, i_t + \varepsilon_t^f. \tag{10}$$

Unemployment responds to financial conditions and not directly to the policy rate. Financial conditions respond to the policy rate and to other forces, ε_t^f, such as changes in risk appetite. Some of these other forces may themselves be policy news that does not move interest rates (Boehm and Kroner, 2024; Bauer et al., 2026). Suppose the economist observes only U_t and i_t. To remove f_t, lag equation (9) one month, multiply it by ρ_f, subtract it from equation (9), and use equation (10). This gives

$$U_t = (\rho_U + \rho_f) \, U_{t-1} - \rho_U \rho_f \, U_{t-2} + \kappa\lambda \, i_{t-1} + \underbrace{\varepsilon_t^U - \rho_f \, \varepsilon_{t-1}^U + \kappa \, \varepsilon_{t-1}^f}_{\text{error}}. \tag{11}$$

The policy rate has no direct effect in this model. It appears in equation (11) because it stands in for financial conditions. The error is a moving average that includes past financial shocks, so a VAR in U_t and i_t with few lags cannot capture it. The VAR is misspecified. With the lags and samples available in practice, this can make the effects of monetary policy harder to measure.

A second problem matters more for the size and sign of the response: the omission changes the experiment being traced. In the announcement windows, the FCI used below rises about 1 unit per percentage point rise in the two-year yield. In an ordinary month, an unexpected rise of 1 percentage point in the two-year yield, measured by the residual of a monthly VAR in unemployment, inflation, the yield and the FCI, comes with a rise in the FCI of only 0.36 to 0.51 unit at the real and r^* steps (0.38 at the nominal step). A VAR without financial conditions traces the typical move in the two-year yield, which comes with a much smaller change in financial conditions than a policy surprise does.

High-frequency surprises help identify the shock, but they do not by themselves fix how it is carried forward. My design therefore does two things. It includes financial conditions in the

system, so that they carry the effects of the surprise forward, as in equation (9). And it measures the immediate effect of the surprise on the two-year yield and on financial conditions directly in the announcement window, where policy news is the main force at work. The measurement of f_t also matters. If activity responds to financial conditions relative to r^*, a measure that ignores r^* differs from the true f_t by a slow-moving error, and that error enters equation (9).

2.2.3 Financial conditions and real activity

A separate literature asks how financial conditions are related to economic activity. Asset prices help forecast output and inflation, but which ones help changes over time (Stock and Watson, 2003). Credit spreads, and especially their excess bond premium component, are strong predictors of activity (Gilchrist and Zakrajšek, 2012). Broad indexes summarize many such series and are used to assess the outlook (Hatzius et al., 2010; Brave and Butters, 2011). Financial conditions are also linked to the risks around growth, not only to its average (Adrian et al., 2019), and their relationship with unemployment may be nonlinear (Kiley, 2020a). Federal Reserve staff now publish a measure of the effect of financial conditions on growth, with weights from large macroeconomic models (Ajello et al., 2023).

This work has a limit that the event-study literature does not. A correlation between financial conditions and later activity need not reflect a causal effect, because financial conditions also respond to the economy. Hatzius et al. (2010) address part of this problem by removing the effects of past growth and inflation from their indicators. The companion note uses the timing in a VAR for the same purpose (FCI note, 2026). The two literatures have complementary strengths. Work on high-frequency surprises identifies policy shocks cleanly but carries them through a small set of variables. Work on financial conditions studies a broad set of variables but does not isolate policy shocks. I bring them together: the weights in my index come from how its components respond to policy news, and the surprise is carried forward through the estimated relationship between that index and the economy.

2.2.4 Policy news beyond interest rates, and risk appetite

Recent work finds that announcements move stock prices and the dollar much more than interest-rate surprises can explain (Boehm and Kroner, 2024; Bauer et al., 2026). My windows show the same pattern. The policy-news surprise explains 80 percent of the variance of the move in the two-year yield, but only 32 percent for the 10-year yield, 31 percent for the S&P 500, 34 percent for the dollar and 48 percent for the FCI. The part of the FCI's move that the surprise does not explain is therefore large.

There are two readings of this unexplained part. On one, it is mostly news unrelated to policy that happens to arrive in the window, and my estimates capture the effects of policy. On the other, much of it is policy news that does not move interest rates, as Boehm and Kroner (2024) and Bauer et al. (2026) argue. Then my estimates are the effects of one dimension of policy news, and the effects of all policy news through financial conditions could be larger. Both readings agree on the channel: policy news reaches the economy through broad financial conditions.

[TO DO: The earlier draft also reported (i) the window ratio by subperiod and by VIX/EBP state, (ii) the effect of a one-standard-deviation move in the unexplained part of the FCI, (iii) Baa/EBP credit, FCI-components and commodity-price robustness. None of these is in the clean package; (iii) credit moves to the EBP robustness subsection (Section 4); regenerate (i) and (ii) in baseline/ only if the paper needs them.]

2.3 Timing assumptions and identification

The shock is the Nakamura–Steinsson policy-news surprise, s_a in equation (1), from the San Francisco Fed's U.S. Monetary Policy Event-Study Database (Acosta et al., 2025). I use the 252 FOMC announcements from January 1996 to July 2026 with all the window measures available (Appendix D). The window runs from 10 minutes before the statement to 60 minutes after the press conference starts, or 30 minutes around the statement when there is no press conference. Identification comes from timing, at three frequencies. Table 1 summarizes the assumptions.

Table 1: Timing assumptions

Frequency	What can move	Assumption	Equation
Window (minutes)	Two-year yield and FCI, by the amounts measured in the window	News about the path of interest rates is the main systematic force in the window, and the only one correlated with the surprise. Unemployment and inflation do not move.	(13)
Daily	Two-year yield and FCI, each day after the announcement	They depend on their own recent history and on the unemployment and inflation of this month and last month.	(14)
Monthly	Unemployment and inflation, from the month after the announcement	Within a month, unemployment and inflation are set first. They respond to financial variables only with a lag of at least one month.	(15)

The window. The window move in the FCI is computed with the weights in equation (3):

$$\Delta F_a = w_B\, \Delta y_a^{10} + w_Q\, \Delta \mathrm{SP}_a + w_D\, \Delta \mathrm{DXY}_a. \tag{12}$$

These are the measures available within the day, and the ones used to estimate the weights. Percent changes in the S&P 500 equal percent changes in CAPE within a window, because earnings are fixed. I express all effects per percentage point on the two-year yield in the window. The effect on the FCI is the ratio of two regression slopes on the surprise, an instrumental-variables estimate with s_a as the instrument:

$$b = \begin{pmatrix} 1 \\ b_F \end{pmatrix}, \qquad b_F = \frac{\sum_a (\Delta F_a - \overline{\Delta F})\,(s_a - \bar{s})}{\sum_a (\Delta y_a^2 - \overline{\Delta y^2})\,(s_a - \bar{s})} = 0.99. \tag{13}$$

This is close to one because the weights are normalized that way. It is not exactly one because this regression includes a constant, which the scaling in equation (1) does not, and because it uses one fewer announcement. Expected inflation and r^* move slowly, so I take the window move to be the same in every version.

The day. On the announcement day, the two-year yield and the FCI shift by the vector b. I use the window move rather than the change over the whole day, because the full-day change contains other news. On later days, the two series move as equation (14) implies. They affect each other only through the daily lags, so no ordering between them is needed within the day. The window fixes their joint move.

The month. Within each month, unemployment and inflation are set first, and markets then respond to them. So in the month of the announcement, unemployment and inflation have not moved. They respond from the next month on, through the monthly average of the daily financial

series. That average depends on when in the month the announcement falls: an announcement late in a month affects few days of that month's average. This is how the model takes the timing of announcements into account, as Jacobson et al. (2026) recommend. The ordering is the familiar recursive one, in which slow-moving macroeconomic variables come before financial variables (Bernanke and Blinder, 1992; Christiano et al., 1999). It also means that the daily equations include the current month's unemployment and inflation, even though those figures are published later. I treat this as a modeling convention: the monthly values summarize conditions that markets observe as the month unfolds.

The key assumptions. Two assumptions carry the results. The first is the usual one in a VAR. Once the shock has been identified, the economy responds to a change in the financial variables in the same way whatever caused it. A policy shock identified by a Cholesky ordering or an external instrument is traced through the same estimated dynamics as every other shock, and I do the same. This has a familiar cost. Stock prices partly anticipate future activity, so a move that policy news pushes through stocks need not act on the economy like a move with another cause. This is the same problem as the information effect in any VAR with a high-frequency shock; as in the companion note, I set it aside.

The second assumption is specific to this paper and has two parts. A standard VAR estimates the effect of the shock on every variable in the system. Here, the surprise reaches unemployment and prices only through the two-year yield and the FCI, and has no direct effect on them in the window. Anything else it moves, such as credit spreads or expectations, is left out. So are the moves in stock prices and the dollar in the window that are unrelated to s_a; the surprise explains only about a third of those moves (Section 2.2.4). The non-yield shock of Boehm and Kroner (2024) is uncorrelated with policy-news surprises, so such moves do not bias b_F. But the weights in equation (3) treat them as noise, and part of them may be policy news (Boehm and Kroner, 2024; Bauer et al., 2026). In addition, the monthly equations see the FCI as a single index. Its weights show how the three components respond to policy news, not how the economy responds to each. So I assume that the three affect unemployment and prices in proportion to those weights.

2.4 A mixed-frequency VAR

Structure. The model has a daily block and a monthly block. Let $x_\tau = (R_\tau, F_\tau)'$ hold the two-year yield and the FCI on day τ, in the same version. Let $m_t = (U_t, \pi_t)'$ hold the two monthly variables. The unemployment gap U_t is the unemployment rate minus the CBO estimate of its natural rate. The CBO estimate does not respond to the surprise, so the response of the gap equals that of the unemployment rate. Inflation is $\pi_t = 1200\,\Delta \ln P_t$, where P_t is the price index for personal consumption expenditures excluding food and energy (core PCE).

The daily block is a VAR in the style of the heterogeneous autoregression of Corsi (2009):

$$x_\tau = \alpha + \sum_{k\in\{1,5,22,66\}} \Phi_k\, \bar{x}^{(k)}_{\tau-1} + \Gamma_0\, m_{t(\tau)} + \Gamma_1\, m_{t(\tau)-1} + \xi_\tau, \tag{14}$$

where $\bar{x}^{(k)}_{\tau-1}$ is the average of x over the k days through $\tau-1$, and $t(\tau)$ is the month of day τ. Averages over about a day, a week, a month and a quarter capture persistence with few coefficients. When the FCI is left out, x_τ is the two-year yield alone.

The monthly block is

$$m_t = c + \sum_{l=1}^{L} A_l\, m_{t-l} + \sum_{l=1}^{L} G_l\, \bar{x}_{t-l} + \theta_1\, t + \theta_2\, t^2 + \zeta_t, \qquad \bar{x}_t = \frac{1}{n_t}\sum_{\tau\in t} x_\tau, \tag{15}$$

with n_t the number of weekdays in month t. The model is a mixed-frequency VAR (Ghysels, 2016). In the language of mixed-data sampling, the weights are equal across days within a month and unrestricted across months (Ghysels et al., 2007; Foroni et al., 2015). The equation contains no current-month term in $\bar{x}_t$, which is the timing assumption of Table 1.

Relation to a monthly VAR and a proxy VAR. Suppose the daily block were replaced by a monthly equation for $\bar{x}_t$, and every announcement occurred on the first day of the month. With $Z_t = (m_t', \bar{x}_t')'$, the model would then be a standard monthly VAR with a recursive ordering, the macroeconomic variables first, and impact vector $(0, 0, b')'$. The daily block adds two things: the position of each announcement in its month, and fast dynamics of the financial variables, estimated on many more observations. A proxy VAR (Gertler and Karadi, 2015; Mertens and Ravn, 2013; Stock and Watson, 2018) instead estimates $Z_t = \sum_l C_l Z_{t-l} + \iota_t$ and uses as an instrument z_t the surprises summed over the month. The effect on the FCI per unit effect on the two-year yield is then

$$\frac{\mathrm{Cov}(\iota_{F,t}, z_t)}{\mathrm{Cov}(\iota_{R,t}, z_t)}. \tag{16}$$

The window ratio b_F in equation (13) has the same form, with three differences. It replaces monthly VAR residuals with changes measured inside the window, which do not depend on how strongly the surprise predicts monthly residuals. It sets the entries for unemployment and inflation to zero rather than estimating them. And it dates each shock to its day rather than summing shocks over a month. Section 3.5 estimates both monthly benchmarks.

The time trend. The baseline monthly equations contain a constant and no time trend. Over 1996–2026, unemployment, inflation and interest rates contain slow movements that a short monthly model may not capture: rates drifted down along with r^*, inflation was low in the 2010s and rose after 2020, and the natural rate of unemployment may have shifted in ways the CBO estimate misses. Section 4 reports a cubic spline trend through the business-cycle peaks, with the real measures of the yield and the FCI.

Estimation and inference. I estimate each block by ordinary least squares, on the same sample: January 1996, the month of the first announcement with all window measures, to September 2026 (369 months, and the weekdays of those months for the daily block). The lagged daily averages and the monthly lags may use earlier observations. 2020 is kept in both blocks; Section 4 drops it. The baseline has $L = 12$ monthly lags, fixed in advance; Appendix B shows 3 and 6. Responses are computed recursively, month by month and day by day, as deviations from a path with no surprise, and averaged over the positions of the announcements within their months (Appendix D). The response of the price level after h months is $\sum_{j=0}^{h} \tilde{\pi}_j/12$. Inference is by a block bootstrap with 500 draws (Künsch, 1989; Jentsch and Lunsford, 2019). Each draw resamples the 369 calendar months in moving blocks of 12 months and uses together the monthly residuals, the daily observations and the announcements of the months drawn, which keeps the dependence between them (Appendix A compares it with a simpler bootstrap). The announcements drawn give new values of b and new positions. The monthly equations are re-estimated on a series rebuilt recursively from the drawn residuals, and the daily block on the drawn daily observations. A response is significant at the 5 or 10 percent level when its 95 or 90 percent interval excludes zero. I report 90 percent intervals, as recent studies in this area do (Bauer and Swanson, 2023a; Caldara and Herbst, 2019; Miranda-Agrippino and Ricco, 2021; Ramey, 2016), and 68 percent intervals, which Jarociński and Karadi (2020) report alongside them. The FCI weights and r^* are held fixed. In large samples a VAR of this kind estimates the same effects as local projections (Plagborg-Møller and Wolf, 2021).

3 Baseline results

3.1 Standard methods after the early 1980s

Standard identification schemes have not delivered conventional effects of monetary policy in samples that start after the early 1980s. Ramey (2016) makes the point with the specification of Christiano et al. (1999): estimated on 1965–1995 it gives the classic responses, but on 1983–2007 "the results change dramatically and imply that increases in the federal funds rate lower the unemployment rate"; a version of the Romer–Romer hybrid VAR gives, on the same later sample, contractionary shocks that "appear to be expansionary", as Barakchian and Crowe (2013) found for 1988–2007; and a proxy SVAR with the Romer–Romer shock as instrument, estimated on 1969–2007, gives a "pronounced, statistically significant price puzzle" (her Figures 1 and 2). Her reading is that, because policy has been conducted well, true monetary shocks are rare, and it is hard to extract shocks that are not contaminated by the central bank's foresight. Caldara and Herbst (2019) find, for 1994–2007 with a proxy SVAR that uses high-frequency surprises, that without a credit spread in the system the response of industrial production is weak and uncertain (about -0.2 percent at the posterior mean, with a credible set that includes positive values), against about -0.75 percent when the excess bond premium is added.

I start from the same two standard methods, estimated on my own data and units, so that they can be compared directly with the model below. Both use the monthly unemployment gap, core PCE inflation and the end-of-month two-year Treasury yield, with 12 lags and no trend. The first is the recursive (Cholesky) VAR of Christiano et al. (1999), with the policy rate ordered last, so that unemployment and inflation do not respond to it within the month. The second is a proxy VAR (Stock and Watson, 2018; Mertens and Ravn, 2013; Gertler and Karadi, 2015), which uses the surprise as an instrument for the policy rate: the instrument is the Nakamura–Steinsson policy news (Nakamura and Steinsson, 2018) summed over the announcements of the month, the same 252 announcements used throughout. All responses are to a 1 percentage point rise in the policy rate. Figure 1 and Table 2 show the results.

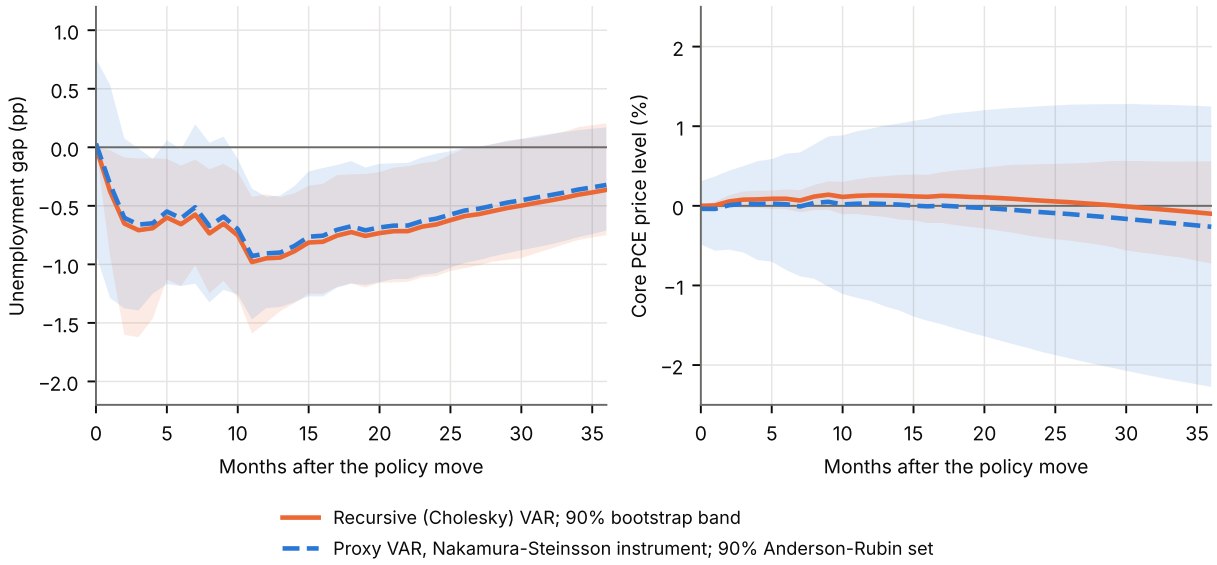

Figure 1: Responses to a 1 percentage point rise in the two-year yield, 1996–2026, from a recursive (Cholesky) VAR and a proxy VAR with the Nakamura–Steinsson instrument. The monthly unemployment gap, core PCE inflation and the two-year yield; 12 lags. Bands: 90 percent (bootstrap for the Cholesky VAR, Anderson–Rubin sets for the proxy VAR, truncated at ±4).

Table 2: Standard methods after the early 1980s: responses to a 1 percentage point rise in the policy rate

			Unemployment gap (pp)			Price level (%)		
Method	Sample	Obs	12 m	24 m	36 m	12 m	24 m	36 m
Cholesky, 2-year yield	1996–2026	369	−0.95*	−0.66*	−0.36	0.13	0.07	−0.10
			[−1.50, −0.40]	[−1.10, −0.12]	[−0.75, 0.21]	[−0.12, 0.36]	[−0.40, 0.52]	[−0.72, 0.56]
Cholesky, 2-year yield	1984–2026	513	−0.61*	−0.36*	−0.16	0.11	0.15	0.13
			[−0.99, −0.20]	[−0.59, −0.05]	[−0.37, 0.16]	[−0.06, 0.29]	[−0.16, 0.45]	[−0.30, 0.51]
Cholesky, federal funds rate	1984–2007	288	−0.04	−0.02	0.00	−0.01	−0.01	0.00
			[−0.09, 0.00]	[−0.06, 0.02]	[−0.03, 0.03]	[−0.08, 0.03]	[−0.11, 0.07]	[−0.12, 0.10]
Proxy VAR, 2-year yield	1996–2026	369	−0.91*	−0.61*	−0.32	0.03	−0.08	−0.26
			[−1.37, −0.42]	[−1.08, −0.05]	[−0.71, 0.17]	[−1.20, 0.97]	[−1.83, 1.25]	[−2.27, 1.25]

Monthly data, 12 lags, constant, no trend; unemployment gap, core PCE inflation and the end-of-month policy rate (the 2-year Treasury yield, or the effective federal funds rate where stated), policy rate ordered last in the Cholesky VARs; price level = cumulated inflation/12. Proxy VAR: Nakamura–Steinsson policy news summed within the month as instrument; first-stage $F = 4.5$. Unit: +1 pp on the policy rate on impact. Brackets: 90% intervals (residual bootstrap for the Cholesky VARs; exact Anderson–Rubin sets for the proxy VAR). * = excludes zero. Specification: baseline/lib/litstyle.py.

In both, unemployment *falls* after a tightening: by 0.95 percentage point after 12 months in the Cholesky VAR and by 0.91 in the proxy VAR. The responses are still negative after 24 months, and the Cholesky VAR gives the same answer when the sample starts in 1984 (−0.61 after 12 months). The price level does not respond in any of them. With the federal funds rate on a 1984–2007 sample, close to the 1983–2007 sample of Ramey (2016), the Cholesky VAR gives the same sign in smaller numbers (−0.04 after 12 months), because a funds-rate innovation is short-lived. Adding a commodity price index, the standard remedy for the price puzzle (Sims, 1992; Ramey, 2016), leaves the two-year-yield response negative (−0.81; Appendix Table A15).

The first-stage F statistic of the proxy VAR is 4.5, in the range in which weak-instrument problems matter (Lewis and Mertens, 2026; Bauer et al., 2026), so I report exact Anderson–Rubin

sets (Montiel Olea et al., 2021; Lunsford, 2015), intervals that stay valid when the instrument is weak. These are the responses when the surprises are traced through the two-year yield alone.

3.2 The FCI model: baseline results

Figure 2 shows the baseline: the response of the unemployment gap and the core PCE price level to a policy move that raises the two-year yield 1 percentage point in the announcement window, from the model of Section 2.4 with the two-year yield and the FCI both measured relative to r^* (solid line, with 68 and 90 percent bands). The dashed line is the nominal two-year yield alone in the same model, and the dash-dotted line is the Cholesky VAR of Section 3.1. The units are the same: the end-of-month two-year yield moves 0.92 to 1.01 of the window move across the steps, so one percentage point in the window and one percentage point on the end-of-month yield in the monthly VARs are the same shock to within about 8 percent.

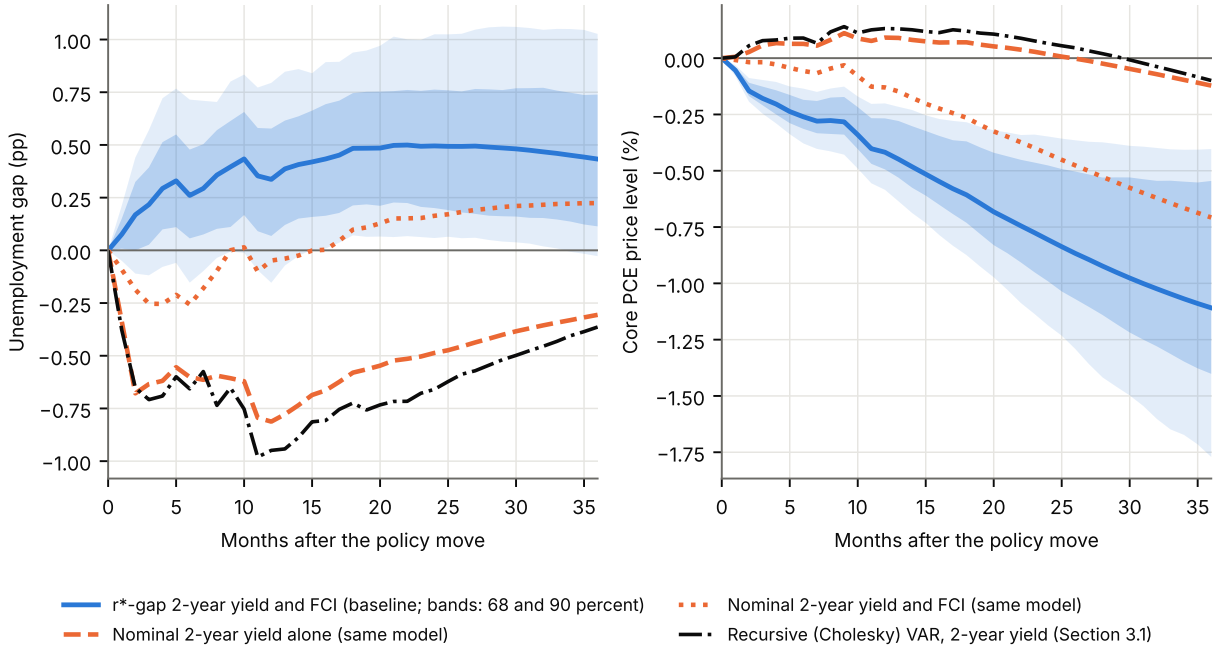

Figure 2: Responses to a policy move that raises the two-year yield 1 percentage point: the baseline (r^*-gap two-year yield and FCI; 12 lags; shaded bands 68 and 90 percent), the nominal two-year yield alone and with the FCI in the same model, and the Cholesky VAR of Section 3.1.

With the nominal yield alone the model gives what the standard methods give: unemployment falls (to −0.81 percentage point after 12 months) and the price level hardly moves. In the baseline unemployment rises (to 0.50 percentage point after 22 months) and the price level falls steadily (by 1.11 percent after 36 months).

The three steps are reported separately in Table 3 and Figure 3. In each step the two-year yield enters alone and then together with the FCI of the same step: nominal measures; real measures, net of expected inflation; and measures relative to r^*, net of expected inflation and of the Laubach–Williams estimate of r^* (Section 2.1 defines them). The tables show 12, 24 and 36 months; the monthly equations have 12 lags, fixed in advance, and Appendix Table A2 shows 3, 6 and 12 lags. The shocks and the monthly equations both start in January 1996, the first announcement for which all window measures are available (369 monthly observations).

Table 3: Baseline: 1996 to the present, all data in, no trend (12 lags)

				Unemployment gap (pp)			Price level (%)		
Case	FCI	Lags	Obs	12 m	24 m	36 m	12 m	24 m	36 m

				[−0.68, 0.10]	[−0.48, 0.25]	[−0.41, 0.34]	[−0.36, −0.04]	[−0.71, −0.09]	[−1.12, −0.17]
	r*-gap	12	369	0.34	0.50^{*}	0.43	-0.42^{**}	-0.81^{**}	-1.11^{**}
				[−0.15, 0.79]	[0.06, 1.02]	[−0.03, 1.03]	[−0.58, −0.20]	[−1.19, −0.35]	[−1.77, −0.40]

Nominal, real and r*-gap 2-year yield; the FCI is Note A's index in the matching form in each case. Per +1 pp on the 2-year yield. ** and *: significant at the 5 and 10 percent levels (the 95% and 90% bootstrap intervals exclude zero); 90% intervals in brackets. Obs = monthly observations in the equations.

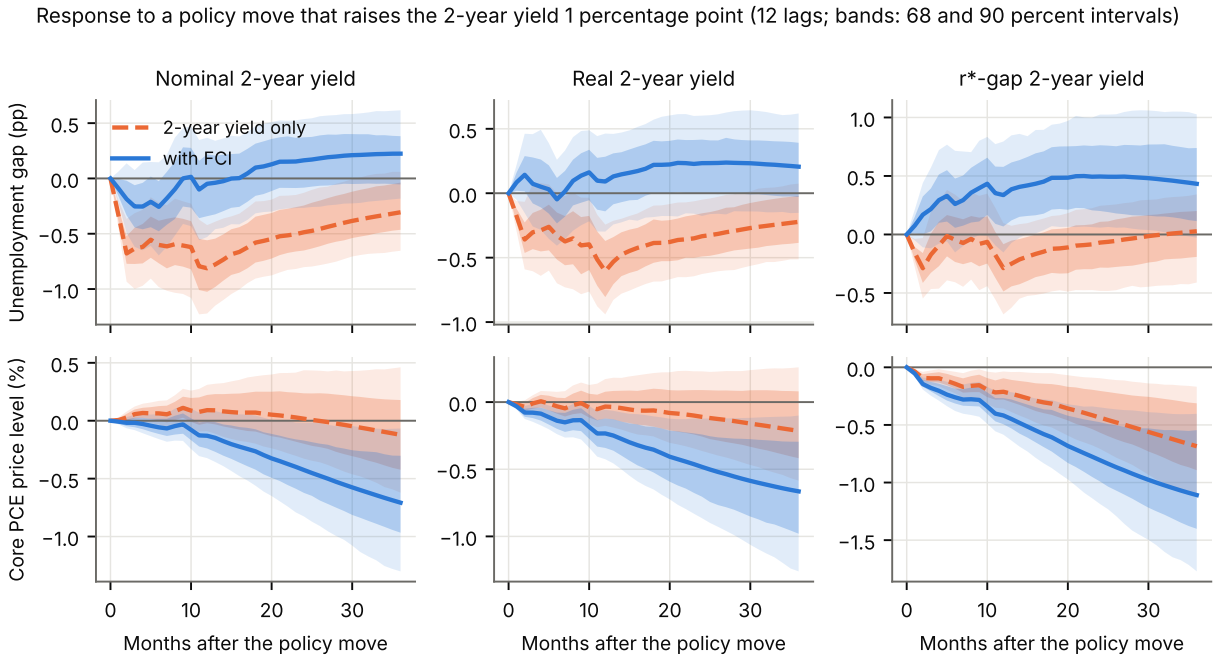

Figure 3: Responses to a policy move that raises the two-year yield 1 percentage point, without and with the FCI (12 lags). Bands: 68 and 90 percent intervals.

Adding the FCI removes the fall in unemployment and lowers the price level at every step, and measuring both relative to r^* gives the largest responses. With the nominal or real yield alone, unemployment falls after a tightening (−0.81 and −0.60 percentage point after 12 months) and the price level does not respond. Relative to r^*, the yield alone raises no unemployment but lowers the price level (−0.44 percent after 24 months). After 24 months, unemployment with the FCI is 0.50 and the price level −0.81 at the r^* step, against 0.16 and −0.43 at the nominal step and 0.23 and −0.48 at the real step. At the r^* step the unemployment response after 24 months is significant at

the 10 percent level (90 percent interval [0.06, 1.02]) and the price response is significant at the 5 percent level at every horizon.

3.3 The implied inflation-unemployment tradeoff

What matters for policy is the ratio of the price response to the unemployment response. Following Barnichon and Mesters (2021), I measure it by the Phillips multiplier at horizon H, the cumulative price response per unit of cumulative unemployment response:

$$\mathcal{P}_H = \frac{\tilde{P}_H}{\tilde{U}_H}, \qquad \tilde{U}_H = \frac{1}{12}\sum_{h=1}^{H} \tilde{U}_h, \tag{17}$$

where $\tilde{P}_H$ is the response of the core price level after H months, in percent, and $\tilde{U}_H$ is the cumulative response of the unemployment gap, in percentage-point years. Because the price level cumulates inflation, $\mathcal{P}_H$ is the cumulative change in inflation per unit of cumulative unemployment. Its inverse, $-1/\mathcal{P}_H$, is a sacrifice ratio: the percentage-point years of unemployment needed to lower the price level 1 percent. A more negative $\mathcal{P}_H$ means a steeper Phillips curve.

$\tilde{U}_H$ can be close to zero, and then the ratio is not well defined. So I form 90 percent sets for $\mathcal{P}_H$ in the spirit of Anderson and Rubin (1949): the set contains every value $\mathcal{P}$ for which the 90 percent bootstrap interval of $\tilde{P}_H - \mathcal{P}\,\tilde{U}_H$ contains zero. The sets are computed exactly, not on a grid, and can be unbounded, which shows when the data cannot pin down the tradeoff. Table 4 reports $\mathcal{P}_{24}$ and $\mathcal{P}_{36}$ for each step and for the main sample variations.

Table 4: Implied trade-off: Phillips multiplier κ_H (12 lags)

Case	FCI	$H = 24$ months	$H = 36$ months
Nominal	none	−0.01 [−0.29, 0.38]	0.08 [−0.24, 0.57]
	nominal	unbounded	unbounded
Real	none	0.14 [−0.25, 0.82]	0.21 [−0.19, 1.15]
	real	unbounded	unbounded
r*-gap	none	unbounded	unbounded
	r*-gap	−1.07 [−4.72, −0.49]	−0.90 [−3.71, −0.37]
Start 1973	r*-gap	unbounded	unbounded
2020 dropped	r*-gap	−0.95 [−1.85, −0.38]	−0.82 [−1.94, −0.22]
2020 dropped, start 1973	r*-gap	−1.49 [−3.37, −0.74]	−1.64 [−5.36, −0.76]
Ends 2019	r*-gap	unbounded	unbounded
Ends 2019, start 1973	r*-gap	−1.21 [−10.65, −0.43]	unbounded
r*-gap minus nominal, with FCI		[−1.55, 7.17]	[−1.50, 5.08]

κ_H = core PCE price level at month H (percent) per percentage-point year of cumulative unemployment-gap response (Barnichon and Mesters 2021); the sacrifice ratio is $-1/\kappa_H$. Point estimate and 90% confidence set (Anderson–Rubin type) in brackets, computed exactly (a wide grid refined by bisection), so a finite end is never an artifact of the grid. An infinite end means that the 90% interval of the cumulative unemployment response includes zero: the data then cannot rule out arbitrarily steep trade-offs on that side; "unbounded": both sides. Last row: paired difference over common announcement draws.

The tradeoff can be measured at the r^* step with the FCI. With the r^*-gap two-year yield and FCI, $\mathcal{P}_{24}$ is −1.07 with a 90 percent set of [−4.72, −0.49] and $\mathcal{P}_{36}$ is −0.90 with [−3.71, −0.37]; both sets exclude zero. A sacrifice ratio is then 0.9 percentage-point years of unemployment per 1 percent of price level after 24 months. At the nominal and real steps with the FCI, and for the r^*-gap yield alone, the sets are unbounded: the cumulative unemployment response is too close to zero to pin

down the ratio. With the nominal or real yield alone, the multiplier is close to zero and the sets include zero: a tightening that does not raise unemployment says nothing about the cost of lowering inflation. When 2020 is dropped the multiplier is −0.95 after 24 months from 1996 and −1.49 from 1973, with sets that exclude zero. The set from 1973 ending in 2019 also excludes zero after 24 months, and the sets for the sample from 1973 and for the sample ending in 2019 are unbounded (Table 4). The last row gives the paired difference between the r^*-gap and the nominal baselines. For comparison, Barnichon and Mesters (2021) report a multiplier of about −0.15 after three to four years for 1990–2008, estimated with high-frequency surprises, and a multiplier that diverges before 1990 and is about −3 after five years, estimated with Romer–Romer shocks. Their multiplier is the ratio of the cumulative response of inflation to the cumulative response of unemployment, as in equation (17). At the baseline horizons it lies between the two: −0.90 after three years.

3.4 Financial conditions in the announcement window

The model assumes that policy reaches unemployment and prices through the two-year yield and the FCI, the broad index of the 10-year yield, equity valuations and the real dollar, weighted by their responses to policy news (Table 5). In the announcement window the FCI moves with the two-year yield: a policy move that raises the two-year yield 1 percentage point raises the FCI by 0.99 (in the same units). A model with the two-year yield alone omits this channel. Figure 4 shows the responses of the two-year yield and the FCI to the policy move in the baseline.

Table 5: Market-index weights from policy news

Component	Response to policy news	Weight	Share of a policy move
10-year Treasury yield (pp)	+0.53 (0.06)	+0.609	0.33
Equity valuation, 100 ln CAPE (%)	−7.78 (0.93)	−0.051	0.40
Real broad dollar, 100 ln (%)	+4.22 (0.53)	+0.065	0.28

Response of each 30-minute announcement-window change to the policy-news factor (scaled so the 2-year yield moves 1 pp), with robust standard errors; weights from the one-factor GLS of Note A; share = weight × response (the three shares sum to 1).

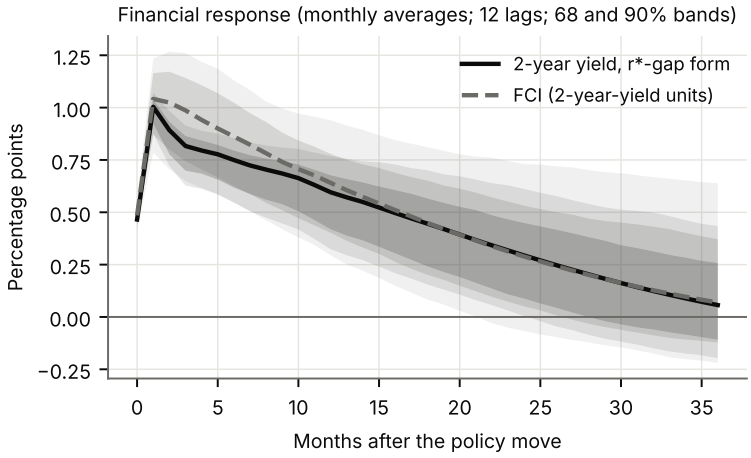

Figure 4: Response of the r^*-gap two-year yield and the FCI (in two-year-yield units) to a policy move that raises the two-year yield 1 percentage point in the window (monthly averages; 12 lags; 68 and 90 percent bands).

3.5 Proxy VARs with the FCI, and a simulation

The monthly VAR can be extended with the end-of-month FCI of the same step and estimated in two ways, with the same 1996 sample and announcements. In the *proxy VAR* the immediate effect of the surprise on every variable is estimated from the monthly residuals and the instrument, as in the VARs without the FCI. In the *window-impact VAR* it is not estimated: the effect on the two-year yield and the FCI is taken from the announcement windows (the model's end-of-month response to a window surprise), and the effect on unemployment and inflation is set to zero within the month, the same restriction as in the main model. Table 6 gives the results at each step.

Table 6: Monthly VAR benchmark (12 lags)

					Unemployment gap (pp)			Price level (%)		
2-year	FCI	Identification	Lags	Obs	12 m	24 m	36 m	12 m	24 m	36 m
Nominal	none	Proxy VAR	12	369	−0.91*	−0.61*	−0.32	0.03	−0.08	−0.26

Monthly VAR in the unemployment gap, core PCE inflation, the end-of-month 2-year yield and, when included, the end-of-month FCI (same step), 1996 to September 2026, no trend, nothing dropped. Proxy VAR: Nakamura–Steinsson surprise as instrument; sets are exact 90% Anderson–Rubin sets, "unbounded" when the instrument cannot reject large effects. Window impact: impact vector taken from the daily model (the end-of-month response to a window surprise); 90% bootstrap intervals. Unit in both: +1 pp on the 2-year yield (the end-of-month response to a +1 pp window surprise is 0.92 to 1.01, so the two units are the same up to 8%). * = 90% interval excludes zero.

The first-stage F statistic of the proxy VAR with the FCI is 4.4 at the r^* step, and Appendix Table A16 reports it for each step. The proxy also implies an end-of-month response of the FCI of 1.44 per percentage point of the two-year yield, against 1.03 in the window. The window-impact VAR is close to the main model: with the r^*-gap yield and FCI, unemployment rises 0.33 percentage point after 12 months and the price level falls 0.77 percent after 24, and without the FCI unemployment does not rise (−0.19 after 12 months).

If the model were the true process, how noisy would the proxy VAR be in samples like mine? I simulate 1,000 samples of 369 months from the estimated r^*-gap model, with the data's calendar and announcement days, resample the daily and monthly innovations and the surprises, and apply the monthly estimators to the end-of-month series of each sample (Table 7).

Table 7: A monthly proxy VAR when the r*-gap model is the true process

Estimate	Data	True	Simulated median	5th–95th percentile
A. Proxy VAR with the FCI				
First-stage F	4.4		11.1	[2.5, 27.2]
Unemployment gap, 12 m	0.95	0.33	0.35	[−0.31, 1.26]
Price level, 24 m	−1.24	−0.80	−0.69	[−1.91, 0.17]
B. Proxy VAR without the FCI				
Unemployment gap, 12 m	−0.33	0.33	0.02	[−0.70, 0.70]
C. Monthly VAR with the window impact and the FCI				
Unemployment gap, 12 m	0.33	0.34	0.35	[−0.10, 0.80]

1,000 samples of 369 months generated by the estimated r*-gap model with the FCI (12 lags), with the data's calendar and announcement days; policy reaches unemployment and prices only through the 2-year yield and the FCI. Data: the 1996 sample, 12 lags, r*-gap measures; end-of-month series in the monthly VAR. True: the model's response per +1 pp on the 2-year yield, in the window (panel C) and on the end-of-month yield (panels A and B; the window response divided by the model's end-of-month response of 0.92–1.01). Simulated: median and 5th–95th percentiles of the estimates.

Under the model the true response of unemployment after 12 months is 0.33 percentage point. The proxy VAR with the FCI is centred on it (median 0.35) with a wide range: the 5th to 95th percentile range is [−0.31, 1.26], and the first-stage F is below the data value (4.4) in 14 percent of samples. Without the FCI the proxy VAR is biased toward zero (median 0.02). The window-impact VAR recovers the truth (median 0.35) with a narrower range. The data values lie inside the simulated ranges. If the model is the true process, a monthly proxy VAR is a noisy way to estimate the effect, and a first-stage statistic and responses like those in the data are what it produces.

4 Robustness

I check the baseline against variations in the sample, the measure of r^*, the trend, credit conditions, the weights of the FCI and the surprise. Each variation changes one feature of the baseline and keeps the rest: the shocks are the same 252 announcements, the monthly equations have 12 lags, and responses are to a policy move that raises the two-year yield 1 percentage point in the announcement window. Each table shows the yield without and with the FCI of the same step, and Appendix tables give 3, 6 and 12 lags.

4.1 The sample

Three variations change the sample. In the first, the monthly equations start in 1973 rather than 1996; the months before 1990, for which there are no daily data, use monthly series in place of the daily block, the daily block is still estimated from 1996, and the shocks are still the announcements from 1996. In the second, March to December 2020 are dropped from the monthly and daily equations (2020 values still enter as lags). In the third, all equations end in December 2019. Each is run with the monthly equations starting in 1996 and in 1973. Table 8 shows the r^*-gap two-year yield without and with the r^*-gap FCI.

Table 8: Robustness 1: sample (r*-gap 2-year yield and FCI) (12 lags)

				Unemployment gap (pp)			Price level (%)

Ends 2019, start 1973	none	12	552	0.19**	0.18	0.08	−0.21**	−0.49**	−0.82**
				[0.04, 0.30]	[−0.03, 0.32]	[−0.15, 0.24]	[−0.32, −0.06]	[−0.71, −0.15]	[−1.18, −0.25]
	r*-gap	12	552	0.27**	0.16	0.09	−0.22**	−0.50**	−0.84**
				[0.04, 0.40]	[−0.16, 0.34]	[−0.26, 0.29]	[−0.32, −0.05]	[−0.72, −0.18]	[−1.23, −0.29]

Start 1973: monthly equations from 1973, with monthly series in place of daily data before 1990 (lib/model.py). 2020 dropped: March to December 2020 removed from the monthly and daily equations (2020 values still enter as lags). Ends 2019: all equations, monthly and daily. Per +1 pp on the 2-year yield. ** and *: significant at the 5 and 10 percent levels (the 95% and 90% bootstrap intervals exclude zero); 90% intervals in brackets. Obs = monthly observations in the equations.

With the FCI, unemployment rises and the price level falls in every variation. The price response is smaller when the sample starts in 1996 and ends in 2019 (−0.14 after 24 months). When the monthly equations start in 1973, the price response appears with the FCI and without it (−0.63 and −0.50 after 24 months).

4.2 The r^* adjustment and trends

Two variations change how slow-moving trends are handled. The first replaces the Laubach–Williams estimate of r^* with Kiley's, in the two-year yield and in the FCI alike. The second uses no r^* measure: it keeps the real two-year yield and the real FCI, and adds a natural cubic spline in time to every monthly equation, with knots at the sample ends and at the NBER business-cycle peaks inside the sample. Table 9 gives the results.

Table 9: Robustness 2: the r* adjustment and trends (12 lags)

				Unemployment gap (pp)			Price level (%)		
Case	FCI	Lags	Obs	12 m	24 m	36 m	12 m	24 m

				[−0.27, 0.06]	[−0.14, 0.27]	[−0.11, 0.24]	[−0.16, 0.01]	[−0.40, −0.05]	[−0.60,
	real	12	633	0.18	0.18	0.11	−0.17**	−0.39**	−(
				[−0.04, 0.38]	[−0.11, 0.44]	[−0.18, 0.34]	[−0.25, −0.04]	[−0.59, −0.14]	[−0.82,

Kiley r*: 2-year minus expected inflation minus Kiley's r*, with Note A's index built with the same r*. Real, spline trend: real 2-year and real FCI with a natural cubic spline trend (knots at the sample ends and at NBER business-cycle peaks inside the sample) in every monthly equation, in place of any r* measure. Per +1 pp on the 2-year yield. ** and *: significant at the 5 and 10 percent levels (the 95% and 90% bootstrap intervals exclude zero); 90% intervals in brackets. Obs = monthly observations in the equations.

With Kiley's r^* the FCI removes the fall in unemployment (−0.53 after 12 months without it, 0.39 with it), and the price response is smaller than in the baseline (−0.18 after 24 months). With real measures and the spline the FCI again removes the fall in unemployment (−0.64 without it, 0.19 with it). From 1973 the price level falls with the FCI in both variations (−0.37 and −0.39 after 24 months).

4.3 Credit conditions

Credit is the most important channel the baseline leaves out (Gilchrist and Zakrajšek, 2012; Caldara and Herbst, 2019). The variation adds the monthly excess bond premium as a third monthly variable, treated like unemployment and inflation, so that the premium responds to the financial variables and they enter its equation as well (Table 10).

Table 10: Robustness 3: excess bond premium (r*-gap) (12 lags)

				Unemployment gap (pp)			Price level (%)		
Case	FCI	Lags	Obs	12 m	24 m	36 m	12 m	24 m	36 m
EBP added	none	12	369	−0.08	0.08	0.16	−0.27**	−0.53**	−0.78**
				[−0.41, 0.22]	[−0.26, 0.37]	[−0.18, 0.45]	[−0.41, −0.09]	[−0.81, −0.18]	[−1.19, −0.27]
	r*-gap	12	369	0.27	0.52*	0.42	−0.39**	−0.78**	−1.10**
				[−0.18, 0.63]	[0.02, 0.96]	[−0.07, 0.96]	[−0.55, −0.18]	[−1.15, −0.32]	[−1.75, −0.37]
EBP added, start 1973	none	12	633	−0.03	−0.01	0.01	−0.22**	−0.50**	−0.78**
				[−0.18, 0.08]	[−0.16, 0.09]	[−0.14, 0.13]	[−0.31, −0.09]	[−0.69, −0.16]	[−1.13, −0.23]
	r*-gap	12	633	0.06	0.03	0.04	−0.24**	−0.57**	−0.89**
				[−0.13, 0.23]	[−0.19, 0.22]	[−0.17, 0.22]	[−0.34, −0.08]	[−0.76, −0.18]	[−1.21, −0.23]

The excess bond premium is a third monthly variable, treated like unemployment and inflation (u, inflation, EBP system); responses shown for u and the price level. Per +1 pp on the 2-year yield. ** and *: significant at the 5 and 10 percent levels (the 95% and 90% bootstrap intervals exclude zero); 90% intervals in brackets. Obs = monthly observations in the equations.

With the r^*-gap FCI, unemployment rises (0.52 after 24 months) and the price level falls (−0.78). Without the FCI the unemployment response is close to zero (−0.08 after 12 months), nearer to zero than in the baseline without the FCI (−0.29).

4.4 The weights of the FCI

The baseline assumes that the three parts of the FCI, the 10-year yield, equity valuation and the dollar, affect unemployment and prices in proportion to the weights with which they respond to policy news (Section 2.3). The variation relaxes this. The three weighted components enter the daily and monthly equations separately, in the step of the two-year yield, in place of the FCI, and each has its own window impact; the three impacts add up to the impact of the FCI. To keep the number of parameters reasonable, the daily block is restricted: each component's equation contains its own 1-, 5-, 22- and 66-day averages and those of the two-year yield, plus the monthly macro variables, and the two-year yield's equation its own averages and the macro variables. That is 48 coefficients in all, against 26 in the baseline daily block with the FCI. The monthly equations have 12 lags and start in 1996 or, as a further variation, in 1973. Table 11 shows the responses.

Table 11: Robustness 4: the FCI replaced by its three weighted components (12 lags)

				Unemployment gap (pp)			Price level (%)		
Case	FCI	Lags	Obs	12 m	24 m	36 m	12 m	24 m	36 m

				[−0.31, 0.56]	[−0.22, 0.69]	[−0.51, 0.50]	[−0.24, 0.15]	[−0.21, 0.52]	[−0.17, 0.86]
r*-gap	components	12	369	0.20	0.22	−0.09	−0.14	0.06	0.35
				[−0.30, 0.60]	[−0.29, 0.70]	[−0.69, 0.43]	[−0.28, 0.04]	[−0.25, 0.40]	[−0.22, 0.95]
Nominal, start 1973	components	12	633	−0.28	−0.24	−0.26	0.10	0.45*	0.92**
				[−0.71, 0.07]	[−0.72, 0.13]	[−0.81, 0.19]	[−0.11, 0.38]	[0.05, 1.21]	[0.22, 2.27]
Real, start 1973	components	12	633	−0.11	−0.14	−0.15	−0.14	−0.05	0.16
				[−0.57, 0.19]	[−0.61, 0.13]	[−0.67, 0.12]	[−0.30, 0.14]	[−0.37, 0.68]	[−0.36, 1.41]
r*-gap, start 1973	components	12	633	0.17	0.16	0.09	−0.35**	−0.60	−0.80
				[−0.33, 0.50]	[−0.38, 0.46]	[−0.37, 0.34]	[−0.51, −0.09]	[−0.89, 0.08]	[−1.24, 0.42]

Components: the 10-year yield, equity valuation and real dollar, each multiplied by its weight, enter separately in the daily and monthly equations in the same step as the 2-year yield, each with its own window impact (the three impacts sum to the FCI's). Baseline rows without the FCI are in the baseline table. Per +1 pp on the 2-year yield. ** and *: significant at the 5 and 10 percent levels (the 95% and 90% bootstrap intervals exclude zero); 90% intervals in brackets. Obs = monthly observations in the equations.

Freeing the weights adds many coefficients and widens the intervals. At the r^* step unemployment still rises (0.20 after 12 months from 1996 and 0.17 from 1973), and from 1973 the price level falls (−0.60 after 24 months), as with the FCI. From 1996 the price response is close to zero (0.06 after 24 months). Table 12 tests the restriction that the coefficients on the three components are equal at each lag, with bootstrap p-values. It is not rejected in the unemployment equation. In the inflation equation it is rejected from 1996 (0.013 at the r^* step) and not from 1973 (0.374).

Table 12: Test of the proportional-weights restriction (12 lags)

	Unemployment gap equation		Core PCE inflation equation	
Step	Wald	Bootstrap p	Wald	Bootstrap p
Nominal	8.9	0.984	41.9	0.053
Real	7.0	0.996	42.9	0.041
r*-gap	21.7	0.399	53.9	0.013
Nominal, start 1973	24.5	0.930	26.0	0.539
Real, start 1973	22.2	0.886	32.4	0.232
r*-gap, start 1973	33.4	0.408	27.9	0.374

Wald statistic (heteroskedasticity-robust, HC1) for the restriction that the coefficients on the three weighted components (10-year yield, equity valuation, dollar) are equal at each lag (24 restrictions), in each monthly equation, and the bootstrap p-value (999 residual draws under the restriction); monthly equations from 1996 (first three rows) and from 1973 (last three), no trend, 2020 in. The unrestricted equation is the one used in Robustness 4.

4.5 The surprise

The baseline uses the Nakamura–Steinsson policy news. Two variations change the surprise. The first uses the orthogonalized surprise of Bauer and Swanson (2023a), which removes the part of each surprise that public information predicts; it is available for announcements through 2019 (201 announcements). The second keeps the Nakamura–Steinsson surprise only for announcements in

which the two-year yield and the S&P 500 move in opposite directions in the window, the sign restriction of Jarociński and Karadi (2020) (157 announcements). Table 13 shows the responses.

Table 13: Robustness 5: alternative surprises (r*-gap) (12 lags)

				Unemployment gap (pp)			Price level (%)		
Case	FCI	Lags	Obs	12 m	24 m	36 m	12 m	24 m	36 m
Bauer-Swanson surprise	none	12	369	−0.29	−0.07	0.03	−0.21**	−0.44*	−0.69**
				[−0.68, 0.09]	[−0.48, 0.25]	[−0.41, 0.34]	[−0.36, −0.04]	[−0.71, −0.09]	[−1.12, −0.17]
	r*-gap	12	369	0.40	0.54**	0.47	−0.44**	−0.84**	−1.15**
				[−0.12, 0.90]	[0.08, 1.11]	[−0.01, 1.14]	[−0.64, −0.21]	[−1.29, −0.36]	[−1.96, −0.41]
Jarocinski-Karadi surprise	none	12	369	−0.29	−0.07	0.03	−0.21**	−0.44*	−0.68**
				[−0.69, 0.10]	[−0.48, 0.24]	[−0.41, 0.34]	[−0.36, −0.04]	[−0.71, −0.09]	[−1.12, −0.17]
	r*-gap	12	369	0.42	0.56**	0.49*	−0.45**	−0.85**	−1.17**
				[−0.07, 0.91]	[0.09, 1.13]	[0.00, 1.13]	[−0.63, −0.22]	[−1.30, −0.38]	[−1.91, −0.42]

Bauer-Swanson: orthogonalized surprise of Bauer and Swanson (2023), announcements through 2019. Jarocinski-Karadi: Nakamura-Steinsson surprise kept when the 2-year yield and the SP 500 move in opposite directions in the window. The window impact and the bootstrap use the events with a surprise. Per +1 pp on the 2-year yield. ** and *: significant at the 5 and 10 percent levels (the 95% and 90% bootstrap intervals exclude zero); 90% intervals in brackets. Obs = monthly observations in the equations.

With the two-year yield alone the responses are the same as in the baseline, because the shock is scaled to the yield. With the FCI they are larger: unemployment rises 0.54 and 0.56 after 24 months, against 0.50 in the baseline, and the price level falls 0.84 and 0.85 percent, against 0.81.

5 Conclusion

Interest-rate surprises around Federal Reserve announcements measure policy shocks well, at least the part of policy news that moves interest rates. The hard part has been tracing their effects on the economy. I kept the surprise as it is and changed how its effects are traced: through broad financial conditions rather than one interest rate, and relative to the neutral rate r^*. Traced this way, the responses of unemployment and prices have the standard signs, where the nominal two-year yield alone and the standard methods give the wrong ones. The ratio of the price response to the unemployment response is of conventional size: lowering the core price level 1 percent costs about 0.9 percentage-point years of unemployment over two years.

Earlier work improves the surprise, by removing the parts that public information predicts or that reveal the Fed's view of the economy (Bauer and Swanson, 2023a; Jarociński and Karadi, 2020), or improves the timing of the outcome (Jacobson et al., 2026), and recent work adds a second, non-yield shock that moves stock prices and the dollar (Bauer et al., 2026; Boehm and Kroner, 2024; Boehm et al., 2026). I leave the surprise as it is and change the channel. The risk-appetite work and mine agree that stock prices and the dollar carry much of the effect of policy; they differ in whether those moves are a separate shock or part of financial conditions. Measuring conditions relative to r^* gives the largest responses and the tradeoff.

For policy, the results support judging the stance by financial conditions relative to r^*, as the FOMC did in 2023 (Powell, 2023), and they explain why the same policy rate can be more or less restrictive at different times. The estimates are effects of surprises. They do not say how much of the 2022–24 disinflation, or of the rise in unemployment, was caused by the tightening; that requires a decomposition of the whole episode.

The broader lesson is that the fall in r^* over the past three decades is more than a fact about

the level of interest rates. Unless rates are measured relative to r^*, that fall also makes the effects of policy, and the cost of lowering inflation, harder to measure.

[TO DO: Appendix: the 3/6/12-lag tables now come from baseline/. Still to check: the data-sources table and the construction text against baseline/data/SOURCES.md (unverified items: EBP file origin, r* vintage, daily CAPE and dollar file, DFF and PPIACO copies).]

A The bootstrap

Every interval in the note comes from the block bootstrap of Section 2.4. A simpler bootstrap resamples the three sources of sampling variation separately: the announcements and the monthly residuals independently across months (with the monthly lags held at their values in the data), and the daily observations in moving blocks of 66 days. I ran it with 12 lags and 500 draws for the nominal, real and r^*-gap two-year yield, each without and with the FCI of the same step. Across the 36 responses at 12, 24 and 36 months, its 90 percent intervals are wider than those of the block bootstrap in 34, by a median of 1.15 times (range 0.99 to 1.40). The two agree on whether a response is significant at the 10 percent level in 34 of the 36 responses and at the 5 percent level in 30. The price response of the baseline is significant at the 5 percent level at every horizon under both. The 90 percent interval of the baseline unemployment response after 24 months is [0.06, 1.02] under the block bootstrap and [0.00, 1.02] under the simpler one.

B Lag length

The baseline uses 12 monthly lags, fixed in advance. Table A1 repeats the main results with 3 and 6 lags. The sample, the announcements and the bootstrap are the same at every lag length: the block bootstrap with 500 draws. The tables that follow give every case at 3, 6 and 12 lags.

The direction of every result is the same at every lag length. With the FCI, the price level falls in all 48 responses (16 cases at 12, 24 and 36 months), and no response of unemployment is significantly negative. Unemployment rises in 34 of the 48 responses with 3 lags, 43 with 6 and 42 with 12. Without the FCI, the Cholesky and proxy VARs show a fall in unemployment at every lag length; the Cholesky fall at 12 months is significant at all three. The weights test gives the same verdicts: in the sample from 1996 it rejects proportional weights in the inflation equation at the 10 percent level and does not reject them in the unemployment equation at the 5 percent level, and in the sample from 1973 it rejects in neither. In the simulation, the median proxy-VAR estimate of the unemployment response with the FCI is close to the true response at every lag length.

The size of the responses and the strength of the evidence increase with the lag length. The median price response with the FCI across the 48 responses is −0.21 with 3 lags, −0.35 with 6 and −0.44 with 12. The baseline price response at 36 months is −0.27, −0.87 and −1.11 percent. The number of significant price responses is 4, 30 and 39 of 48. The Phillips multiplier is bounded at 12 lags only; with 3 or 6 lags the data do not rule out arbitrarily steep trade-offs.

Table A1: The main results with 3, 6 and 12 monthly lags

	3 lags	6 lags	12 lags
Standard methods (per +1 pp on the policy rate)			
Cholesky, 2-year yield: unemployment gap, 12 m	−0.64* [−1.01, −0.15]	−0.56* [−0.97, −0.12]	−0.95* [−1.50, −0.40]
Cholesky, 2-year yield: price level, 36 m	0.09 [−0.49, 0.47]	−0.08 [−0.74, 0.36]	−0.10 [−0.72, 0.56]
Proxy VAR: unemployment gap, 24 m	−0.43* [−0.64, −0.10]	−0.36 [−0.76, 0.34]	−0.61* [−1.08, −0.05]
FCI model, r-gap 2-year yield (baseline)*			
With FCI: unemployment gap, 24 m	0.13 [−0.27, 0.48]	0.36 [−0.09, 0.79]	0.50* [0.06, 1.02]
With FCI: price level, 24 m	−0.25 [−0.64, 0.17]	−0.63* [−1.04, −0.15]	−0.81* [−1.19, −0.35]
With FCI: price level, 36 m	−0.27 [−0.78, 0.26]	−0.87* [−1.49, −0.18]	−1.11* [−1.77, −0.40]
Without FCI: unemployment gap, 12 m	−0.17 [−0.47, 0.11]	−0.09 [−0.41, 0.22]	−0.29 [−0.68, 0.10]
Phillips multiplier, 24 m	−0.65 [unbounded]	−1.07 [unbounded]	−1.07 [−4.72, −0.49]
All cases with the FCI in Sections 3 and 4 (16 cases, 3 horizons, 48 responses each)			
Price level falls	48 of 48	48 of 48	48 of 48
Price level falls significantly	4 of 48	30 of 48	39 of 48
Unemployment gap rises	34 of 48	43 of 48	42 of 48
Unemployment gap rises significantly	3 of 48	9 of 48	10 of 48
Financial weights and simulation (r-gap)*			
Proportional weights, 1996: bootstrap p, unemployment equation	0.201	0.236	0.399
Proportional weights, 1996: bootstrap p, inflation equation	0.017	0.050	0.013
Proportional weights, 1973: bootstrap p, inflation equation	0.609	0.752	0.374
Proxy VAR with FCI, simulated: median unemployment, 12 m (true value)	0.25 (0.25)	0.36 (0.33)	0.35 (0.33)
Proxy VAR with FCI, simulated: first-stage F, median	12.2	11.8	11.1

Same sample (1996 to 2026), announcements and block bootstrap (500 draws) at every lag length. Responses per +1 pp on the policy rate; **, *: 95% and 90% intervals exclude zero; 90% intervals in brackets. Counts (at the 10 percent level): the 16 cases with the FCI in the baseline and Robustness 1, 2, 3 and 5 (components excluded), responses at 12, 24 and 36 months.

C Additional tables

Table A15: Standard methods with a commodity price index in the first block

			Unemployment gap (pp)			Price level (%)		
Method	Sample	Obs	12 m	24 m	36 m	12 m	24 m	
Cholesky + commodity prices, 2-year yield	1996–2026	369	−0.81*	−0.44	−0.13	0.11	0.06	
			[−1.24, −0.28]	[−0.83, 0.03]	[−0.45, 0.34]	[−0.12, 0.35]	[−0.36, 0.48]	[-
Cholesky + commodity prices, federal funds rate	1984–2007	288	−0.03	−0.02	−0.01	−0.02	−0.04	
			[−0.07, 0.01]	[−0.06, 0.03]	[−0.04, 0.04]	[−0.09, 0.02]	[−0.13, 0.05]	[-

Monthly data, 12 lags, constant, no trend; unemployment gap, core PCE inflation and the end-of-month policy rate (the 2-year Treasury yield, or the effective federal funds rate where stated), policy rate ordered last in the Cholesky VARs; price level = cumulated inflation/12. The log PPI for all commodities (monthly average) is added to the system and ordered before the policy rate. Unit: +1 pp on the policy rate on impact. Brackets: 90% intervals (residual bootstrap for the Cholesky VARs; exact Anderson–Rubin sets for the proxy VAR). * = excludes zero. Specification: baseline/lib/litstyle.py.

Table A2: Baseline: 1996 to the present, all data in, no trend

The 10-year yield, equity valuation and the real dollar, each multiplied by its weight, enter the daily and monthly equations separately, in the same step as the 2-year yield; each has its own window impact. Replaces the FCI, so the same step without the FCI is the baseline row. Per +1 pp on the 2-year yield. ** and *: significant at the 5 and 10 percent levels (the 95% and 90% bootstrap intervals exclude zero); 90% intervals in brackets. Obs = monthly observations in the equations.

Table A16: Monthly proxy VAR: first-stage strength and impact on the FCI

2-year	FCI	F (3 lags)	F (6)	F (12)	Proxy impact on FCI	Model impact on FCI
Nominal	none	5.0	4.6	4.5		
	nominal	2.7	2.1	1.6	1.73	1.13
Real	none	9.0	7.3	6.9		
	real	6.0	4.2	3.0	1.50	1.03
r*-gap	none	9.1	8.2	8.0		
	r*-gap	8.4	6.7	4.4	1.44	1.03

F: robust first-stage statistic of the policy-variable residual on the instrument (instrument months only, 1996–2026). Impact on FCI: end-of-month response of the FCI per +1 pp on the end-of-month 2-year yield, estimated from monthly residuals (proxy VAR, 12 lags) and implied by the daily model.

D Construction and estimation details

Events. I use the 252 FOMC announcements from January 1996 to July 2026 with all the window measures available in the U.S. Monetary Policy Event-Study Database (Acosta et al., 2025). As in the companion note, I leave out unscheduled announcements with no change in the policy rate, and March–April 2020. The announcements of September and October 2026 are left out because too few later days are available. The DXY index used in the window covers fewer currencies than the broad dollar used in the daily and monthly index, which I treat as a measurement difference.

From monthly to daily. Expected inflation and r^* are not available daily, and they move slowly. I take the monthly gap between R_t^v in equation (8) and y_t^2, interpolate it linearly between the middles of adjacent months, and add it to the daily yield. The daily index is

$$F_\tau^v = w_B\, y_\tau^{10} + w_Q\, 100 \ln \mathrm{CAPE}_\tau + w_D\, 100 \ln \mathrm{DOL}_\tau + o_\tau^v, \tag{18}$$

where DOL_τ is the daily nominal broad dollar. The offset o_τ^v is the monthly difference between the index in equation (4) and the average of the first three terms, interpolated in the same way. It also absorbs the difference between the real and the nominal dollar. The monthly averages of the daily series are very close to the monthly measures: the root-mean-square difference is at most 0.02 unit for the FCI and 0.04 percentage point for the two-year yield. The offsets change little from day to day, so day-to-day moves in the index come from market prices. Table A18 shows the measures used at each frequency. The daily calendar has every weekday; missing values, such as on holidays, are filled from the previous observation for up to three days. Each daily equation has 13 coefficients with the FCI; each monthly equation has $1 + 4L$ with the FCI and $1 + 3L$ without it.

Table A18: Measures of stocks and the dollar at each frequency

Frequency	Stocks	Dollar
Window	S&P 500	DXY index
Daily	CAPE	Nominal broad dollar, plus offset
Monthly	CAPE, or earnings-yield gap to r^*	Real broad dollar

Tracing the effect of a surprise. The response is computed recursively, as a deviation from a path with no surprise. Let the announcement occur on weekday d_0 of the announcement month, and let $h = 0, 1, \ldots, 36$ count months from then. Tildes denote responses.

1. In each month, unemployment and inflation come first: $\tilde{m}_0 = 0$, and for $h \geq 1$,

$$\tilde{m}_h = \sum_{l=1}^{L} A_l \, \tilde{m}_{h-l} + \sum_{l=1}^{L} G_l \, \tilde{x}^M_{h-l}, \tag{19}$$

   with terms dated before the announcement month equal to zero, and $\tilde{x}^M_h$ the response of the monthly average of x.

2. The days of the month follow. Before day d_0, $\tilde{x}_\tau = 0$. On day d_0, $\tilde{x}_\tau = b$ from equation (13). On every later day, with $\tilde{x}^{(k)}_{\tau-1}$ the average of the responses over the k days through $\tau - 1$,

$$\tilde{x}_\tau = \sum_{k \in \{1,5,22,66\}} \Phi_k \, \tilde{x}^{(k)}_{\tau-1} + \Gamma_0 \, \tilde{m}_{h(\tau)} + \Gamma_1 \, \tilde{m}_{h(\tau)-1}, \tag{20}$$

   where $h(\tau)$ is the month of day τ, counted from the announcement month.

3. The monthly average $\tilde{x}^M_h$ then enters equation (19) for later months.

Months after the announcement month have 21 weekdays. To avoid computing a path for every date, I form six groups of announcement dates by the weekday of the month, in blocks of four days, and compute the path at each group's average day and month length. With ω_g the share of announcements in group g, the reported response is $\sum_g \omega_g \, \tilde{m}^{(g)}_h$. Because the model is linear, these responses do not depend on the constant or the trend.

Bootstrap. In each of 500 draws, I resample the 252 announcements with replacement, which gives new values b^* in equation (13) and new group shares ω^*_g. I also resample the residuals $\hat{\zeta}_t$ of equation (15) jointly across equations, add them to the fitted values, holding the regressors fixed, and re-estimate the monthly block. I also re-estimate the daily block on a moving-block resample of its rows (blocks of 66 days, the longest averaging window). I compute the response for each draw and report percentile intervals. The sets for the Phillips multiplier in Table 4 use the same 500 draws, with the announcement draws shared across steps.

E Data sources

Table A19 lists the data. Series from FRED are identified by their mnemonics. Quarterly series are placed in the middle month of the quarter and interpolated linearly.

Table A19: Data sources

Series	Frequency	Source
Unemployment rate	Monthly	FRED UNRATE
Natural rate of unemployment	Quarterly	CBO, FRED NROU
Core PCE price index	Monthly	FRED PCEPILFE
Two-year Treasury yield	Daily	FRED DGS2; before June 1976, the Gürkaynak–Sack–Wright zero-coupon yield (Federal Reserve Board)
10-year Treasury yield	Daily, monthly	FRED DGS10, GS10
Expected inflation, 1, 2 and 10 years	Monthly	Cleveland Fed, FRED EXPINF1YR, EXPINF2YR, EXPINF10YR; before 1982, Livingston Survey (Philadelphia Fed)
r^*, Laubach–Williams	Quarterly	New York Fed, one-sided estimates (data through 2026Q2)
r^*, Kiley	Quarterly	One-sided estimates of the author
CAPE	Monthly	Shiller, spliced over 1990–92 to the monthly average of daily CAPE
Daily CAPE	Daily	S&P 500 (FRED SP500) over Shiller's 10-year earnings, constructed by the daily workflow of the repository
Real broad dollar	Monthly	FRED RTWEXBGS, spliced to TWEXBPA in 2006
Nominal broad dollar	Daily	FRED DTWEXBGS; earlier DTWEXB, TWEXBMTH
Excess bond premium	Monthly	Gilchrist and Zakrajšek (2012), Federal Reserve Board
Federal funds rate; commodity prices	Daily; monthly	FRED DFF; FRED PPIACO (producer price index, all commodities)
Futures, yields, S&P 500 and DXY in the window	Event	U.S. Monetary Policy Event-Study Database, "monetary events" (Acosta et al., 2025)
Orthogonalized surprise	Event	Bauer and Swanson (2023a), posted data (announcements through 2019)
