Financial Conditions, r^*, and the Transmission of Monetary Policy Surprises

Draft for discussion

9 November 2026

Abstract

Monetary policy is the main tool for stabilizing the economy, but recent estimates of its effects are troubling. Surprise tightenings often have small or wrong-signed effects on unemployment and inflation. Read through a Phillips curve, the estimates imply that lowering inflation is very costly. We keep standard interest-rate surprises around Federal Reserve announcements and change only how their effects are traced through the economy. We build in two well-established features of how policy works. It acts through financial conditions as a whole, not through one interest rate. And what matters is the level of rates relative to the neutral rate r^*, the rate that neither stimulates nor restrains the economy. Traced through the two-year yield alone, the surprises give the familiar wrong signs. Traced through a broad financial conditions index measured relative to r^*, they give standard and precisely estimated effects. A policy move that raises the two-year yield 1 percentage point raises the unemployment rate about 0.4 percentage point and lowers industrial production about 1 percent within a year. It lowers the core price level about 0.6 percent after two years. The implied tradeoff between inflation and unemployment is much steeper than recent estimates of a flat Phillips curve, and steeper than when conditions are measured in nominal terms. Financial conditions matter most for the unemployment result. Measuring them relative to r^* matters most for the price result and the tradeoff, which rely on data since 2020.

[TO DO: Abstract: rewrite last, after Section 3 is final. It must state the three problems, the baseline (r*-gap 2-year yield and FCI, no trend, 12 lags) and where the price result is conditional.]

1 Introduction

Monetary policy is the main tool for stabilizing the economy. Its use rests on estimates of how much a change in policy moves unemployment and inflation. Those estimates have become harder to defend. In samples since the mid-1990s, a surprise tightening often has small effects on unemployment, or effects of the wrong sign (Ramey, 2016). Its effects on inflation look smaller still. Two concerns follow. One is that policy has become less powerful (Boivin and Giannoni, 2006; Boivin et al., 2010). The other is that inflation responds little to slack: the Phillips curve is flat (Hazell et al., 2022; Del Negro et al., 2020), so lowering inflation requires a large and lasting rise in unemployment. If both were true, policy would be weaker and more costly than standard models suggest. This paper asks whether these findings reflect how policy works or how its effects are measured.

The question matters in practice. From 2022 to 2023 the Federal Reserve raised its policy rate by more than 5 percentage points. Policymakers expected costs: in August 2022 the Chair warned

of "some softening of labor market conditions" and called these "the unfortunate costs of reducing inflation" (Powell, 2022). They also described policy as working through broad financial conditions. In November 2023 the Chair noted that "Financial conditions have tightened significantly in recent months, driven by higher longer-term bond yields, among other factors" (Powell, 2023). Yet the standard tools for measuring the effects of policy leave those conditions out.

Interest-rate surprises around Federal Reserve announcements were meant to settle the measurement problem. The FOMC makes its decision before the announcement, so market moves in a narrow window around the announcement, at most about 100 minutes long, cannot have caused the decision. The change in interest-rate futures and Treasury yields in that window is then news about policy, or at least about the part of policy that moves interest rates (Kuttner, 2001; Gürkaynak et al., 2005). These surprises measure the effects of policy on asset prices precisely (Bernanke and Kuttner, 2005; Hanson and Stein, 2015; Nakamura and Steinsson, 2018; Swanson, 2021). But when they are used to measure effects on unemployment and inflation, the old puzzles often return. Recent work offers several explanations, each with a fix, and the fixes complement one another.

- *Information.* An announcement reveals the Fed's view of the economy as well as its policy, so a surprise tightening can signal good news (Romer and Romer, 2000; Nakamura and Steinsson, 2018). Separating the two gives larger price effects (Jarociński and Karadi, 2020; Miranda-Agrippino and Ricco, 2021).
- *Predictable surprises.* Part of each surprise can be predicted from earlier public data. Removing it, and adding surprises from the Chair's speeches, gives larger and more precise effects (Bauer and Swanson, 2023a,b).
- *Timing.* Markets react within minutes, but unemployment and inflation are monthly averages. Measuring inflation daily removes most of the wrong-signed response (Jacobson et al., 2026).
- *Credit and risk appetite.* Credit costs carry part of the effect (Gertler and Karadi, 2015; Caldara and Herbst, 2019). Announcements also move stock prices and the dollar much more than interest-rate surprises can explain. Treated as a separate shock, this news has large effects (Kroencke et al., 2021; Bauer et al., 2023; Boehm and Kroner, 2024; Bauer et al., 2026; Boehm et al., 2026).

Most of this work, however, traces the surprise forward through a single interest rate, measured in nominal terms. That leaves out two basic parts of how monetary policy works.

First, policy affects spending through financial conditions as a whole: the cost of long-term credit, the value of wealth and the exchange rate (Boivin et al., 2010). A surprise tightening moves long-term yields, stock prices and the dollar, not only the two-year yield. A model that omits these variables traces the wrong experiment. The financial conditions index (FCI) used below combines the 10-year yield, stock valuations and the dollar. It is scaled so that, in the announcement windows, it rises about 1 unit per percentage point rise in the two-year yield. In ordinary months it moves only about 0.35 to 0.4 unit per point. A model with the two-year yield alone therefore traces the typical move in that yield. That move comes with a much smaller change in financial conditions than a policy surprise brings.

Second, what matters for spending and inflation is the level of real interest rates compared with the neutral rate r^*, the rate that neither speeds up nor slows down the economy. The neutral rate fell a lot from the 1990s to the 2010s (Laubach and Williams, 2003; Holston et al., 2017, 2023; Hamilton et al., 2016; Kiley, 2020b), and it shaped the long-run trend in yields (Bauer and Rudebusch, 2020). Since 1994, interest rates have trended down along with r^*, while activity has trended up. A model that links the level of rates to activity then partly picks up these opposite trends, and finds that higher rates go with stronger activity. Activity responds to changes in financial conditions, but

inflation depends on how long real rates stay above or below r^*. So measuring rates relative to r^* should matter most for prices.

Our contribution is to hold the surprise fixed and change only the variables that carry it to the economy. Broad financial conditions, measured relative to r^*, replace a single nominal rate. Doing so removes the post-1994 wrong-signed unemployment response. It also gives price and output effects comparable to cleaned-shock benchmarks, and a tradeoff much steeper than recent post-1990 estimates.

Our design is simple. The shock is the policy-news surprise of Nakamura and Steinsson (2018), measured in narrow windows around 252 FOMC announcements from 1996 to 2026. We measure its effect on the two-year yield and on the FCI within these windows, and assume that unemployment and inflation do not move within them. A daily model then traces how the two-year yield and the FCI evolve after each announcement. Monthly unemployment and core inflation then respond to the monthly averages of these daily series, as in a standard vector autoregression (VAR). Like Jacobson et al. (2026), we take into account when each announcement falls within its month. The FCI and the order of steps (nominal, real, then relative to r^*) come from a companion note on financial conditions and were fixed before this analysis (FCI note, 2026).

We build up the channel from policy to the economy in four steps. Every step includes a smooth quadratic time trend in the monthly equations. Below, "significant" means that the 90 percent interval excludes zero.

- With the nominal two-year yield as the only channel, the post-1994 puzzles appear. The unemployment response changes sign with the number of monthly lags and is significantly negative with 12. Prices barely move, and industrial production rises.
- Adding the FCI makes the unemployment response standard, large and significant. Prices fall only a little.
- Measuring rates in real terms changes little.
- Measuring the two-year yield and the FCI relative to r^* completes the picture. Unemployment rises 0.36 to 0.40 percentage point after 12 months. The core price level falls 0.53 to 0.72 percent after 24 months. Industrial production falls about 1 percent after 12 months. All are significant for every number of lags.

These effects are not small. Per point on the two-year yield, the unemployment effect is about twice that of the benchmark of Bauer and Swanson (2023a), and the price effect is similar for two years and larger after that.

The results also bear on the inflation-unemployment tradeoff. We measure it by the "Phillips multiplier" of Barnichon and Mesters (2021): the fall in the price level per percentage-point-year of higher unemployment. With financial conditions measured relative to r^*, the multiplier is about -0.8 to -1.1 after two years and -0.5 to -0.85 after three, and its 90 percent sets exclude zero. With conditions measured in nominal terms, it is about half as large and not significantly different from zero. With the two-year yield alone, it cannot be measured at all. Our estimates are much steeper than the post-1990 estimate of Barnichon and Mesters (2021), about -0.15, which lies outside our sets. They are flatter than the pre-1990 estimate in that paper, and flatter than the tradeoff implied by the benchmark of Bauer and Swanson (2023a), whose price effects are similar to ours but whose unemployment effects are smaller.

The steps play different roles. Within our design, the FCI delivers the unemployment result, with its response to the surprise measured in the window. Without the FCI, no adjustment of the two-year yield gives a reliable unemployment response. With it, every adjustment does. Measuring conditions relative to r^* delivers the price result. The unemployment result holds however we treat

the pandemic and is larger in a sample that ends in 2019. The price result, and with it the steeper tradeoff, depends on data from 2020–22, which include the large tightening relative to r^* after 2021: in a sample that ends in 2019, the multiplier is close to zero. The results hold with the cleaned surprises of Bauer and Swanson (2023a) and the pure-policy surprises of Jarociński and Karadi (2020). Two limits stand out. First, credit conditions offer a partial alternative: the excess bond premium, a corporate bond spread net of expected default, also removes the wrong-signed unemployment response without the FCI. Second, adding the FCI to a standard monthly proxy VAR, which uses the surprise as an instrument, is not enough. The FCI's response to the surprise must be measured in the window.

[TO DO: Introduction: restate around the three problems in the literature (perverse responses; effects hard to find in recent decades; implausible sacrifice ratio); update the roadmap paragraph to the new section order; numbers as in Section 3.]

1.1 Connection to the literature

Identifying the effects of policy. Our paper is closest in spirit to Jacobson et al. (2026). Like them, we hold the surprise and the method fixed and change one measurement. They change how often the outcome is measured; we change how the channel from policy to the economy is measured. They study inflation only, while our main result is for activity. Both changes remove wrong-signed responses, and both point to a mismatch between what the economist measures and what drives decisions. Bauer and Swanson (2023a) and Jarociński and Karadi (2020) improve the surprise itself. In our design a surprise enters only through its immediate effect on the two-year yield and the FCI, and through its timing. Their cleaned surprises change our results little and make them slightly stronger, so their fixes and ours can be combined. Our approach also changes which assumptions the estimates rest on. It depends less on how strongly the surprise moves rates over a month, and less on its link to earlier news. It relies instead on the assumption that the economy responds to a given change in financial conditions in the same way, whatever caused it.

The use of futures-based surprises in monthly models goes back to Faust et al. (2004). The choice of surprise series can matter (Bu et al., 2021; Brennan et al., 2025), and so can the number of lags (Coibion, 2012). Related work on timing and mixed frequencies includes Kilian (2024), Chudik and Georgiadis (2022), Francis et al. (2011), Ghysels (2016) and Gazzani and Vicondoa (2020).

Financial channels and risk appetite. Gertler and Karadi (2015) and Caldara and Herbst (2019) are closest in emphasizing financial channels. We use a broad index and measure it relative to r^*, but leave credit spreads out of the baseline. Recent studies of risk appetite and the "non-yield" shock, the announcement news that moves stocks and the dollar beyond what interest rates explain, differ from ours in where they place risk premia (Bauer et al., 2026; Boehm and Kroner, 2024; Boehm et al., 2026). They treat policy-driven moves in risk premia as a second shock; we treat them as part of financial conditions. The channels are the same in both views: stock prices, the dollar and credit costs. Our estimates keep only the part of the stock and dollar moves that comes with interest-rate news, so they measure the effects of that dimension of policy, not of all policy news. The response of stock prices to policy-driven moves in long rates has also changed over time (Kiley, 2014). Section 2.2.4 shows how large the rest is. Caballero et al. (2026) propose a neutral level of the FCI itself, FCI*, because r^* must otherwise absorb asset-price movements that the index already captures. We keep r^* for the rates inside the two-year yield and the index; using gaps to FCI* is a natural extension.

The power of policy and the Phillips curve. A long literature finds that the effects of policy shocks became smaller after the early 1980s. It attributes the change to a more systematic response of policy and to better-anchored expectations (Boivin and Giannoni, 2006; Boivin et al.,

2010; Primiceri, 2005). Others argue that standard identification fails after the late 1980s because policy became more forward-looking (Barakchian and Crowe, 2013). Our results do not suggest that policy has lost power. Our effects are larger than in samples that start in the 1970s, though that comparison is not a formal test of change over time.

On the Phillips curve, recent work finds a small slope (Hazell et al., 2022; Del Negro et al., 2020; Ball and Mazumder, 2019; Fitzgerald et al., 2024). It also stresses that the slope is hard to identify when policy offsets demand shocks (McLeay and Tenreyro, 2020), and that conventional methods tend to understate it (Barnichon and Mesters, 2020). Policy shocks offer one way to identify it. Barnichon and Mesters (2021) measure the tradeoff by the ratio of cumulative inflation to cumulative unemployment after such shocks. In that metric they find a much flatter tradeoff after 1990 than before. Responses to policy shocks also map directly into the outcomes of alternative policies (McKay and Wolf, 2023). We add evidence of this kind and show that the measured tradeoff depends on how the stance of policy is measured. Our price result relies on 2020–22, when inflation surged and then began to fall. Others read that episode as evidence of a steeper, nonlinear Phillips curve (Benigno and Eggertsson, 2023), or as the unwinding of supply shocks (Bernanke and Blanchard, 2025); we return to this in Section 4.1.

2 Empirical approach

The model has three pieces. A surprise moves the two-year yield and the FCI by amounts measured in the announcement window: the vector b in equation (13). A daily VAR, equation (14), carries those two series forward. Their monthly averages then enter a monthly VAR for unemployment and inflation, equation (15). Section 2.1 defines the FCI, Section 2.3 sets out the timing assumptions at each frequency, and Section 2.4 gives the model. Appendix B gives the daily construction of the series, the algorithm for tracing responses and the bootstrap. Appendix C lists the data.
[TO DO: Overview: rewrite for the new Section 2 (2.1 data and measurement; 2.2 why financial conditions and r*; 2.3 timing and identification; 2.4 the model).]

2.1 Measuring financial conditions

The FCI is the market index of FCI note (2026): a weighted sum of the 10-year Treasury yield, stock valuations and the real broad dollar. Indexes of this kind are weighted sums of financial variables (Hatzius et al., 2010). They differ mainly in where the weights come from. FCI-G takes them from large macroeconomic models (Ajello et al., 2023). Ours come from the event-study regressions long used to measure how asset prices respond to policy (Kuttner, 2001; Bernanke and Kuttner, 2005; Hanson and Stein, 2015; Nakamura and Steinsson, 2018).

Policy news. Let ΔX_a be the 5×1 vector of changes in the current- and next-meeting federal funds futures and the second to fourth eurodollar futures in the window around announcement a. Following Nakamura and Steinsson (2018), let p_a be the first principal component of these changes, signed so that it moves with the fourth eurodollar future. Policy news is p_a rescaled so that one unit moves the two-year yield y^2 by 1 percentage point:

$$s_a = \gamma\, p_a, \qquad \gamma = \frac{\sum_a p_a\, \Delta y_a^2}{\sum_a p_a^2}. \tag{1}$$

Weights. Let ΔA_a be the vector of changes in the 10-year yield, the S&P 500 and the DXY dollar index in the announcement window. The companion note treats these changes as

$$\Delta A_a = \psi\, s_a + \eta_a, \tag{2}$$

where ψ holds the policy responses and η_a is other news, with covariance matrix Σ. It estimates ψ by regressing each element of ΔA_a on s_a and a constant, and Σ from the residuals, over 253 announcements from January 1996 to September 2026. The weights are those that recover the policy component most precisely (one-factor generalized least squares):

$$w = \frac{\Sigma^{-1}\psi}{\psi'\Sigma^{-1}\psi}. \tag{3}$$

Because $w'\psi = 1$ and s_a is scaled to the two-year yield, a policy move that raises the two-year yield 1 percentage point raises the index by 1 unit. The weights are 0.61 on the 10-year yield, -0.051 per percent on stock valuations and 0.065 per percent on the dollar. Each of the three accounts for about a third of the index's response to policy.

Three versions. In month t, the index in version v is

$$F_t^v = w_B\, B_t^v + w_Q\, Q_t^v + w_D\, D_t, \tag{4}$$

measured as a deviation from its sample mean. Here D_t is 100 times the log of the real broad dollar in every version. With y_t^{10} the 10-year yield, π_t^{10} 10-year expected inflation, and $(E/P)_t$ the inverse of the cyclically adjusted price-earnings ratio (CAPE), the other two terms are:

$$\text{Nominal:} \quad B_t = y_t^{10}, \qquad Q_t = 100 \ln \text{CAPE}_t, \tag{5}$$

$$\text{Real:} \quad B_t = y_t^{10} - \pi_t^{10}, \qquad Q_t = 100 \ln \text{CAPE}_t, \tag{6}$$

$$r^*\text{-gap (baseline):} \quad B_t = y_t^{10} - \pi_t^{10} - r_t^*, \qquad Q_t = -\frac{100}{\overline{E/P}}\left[(E/P)_t - r_t^*\right]. \tag{7}$$

In the r^*-gap version, stocks are measured by the gap between their earnings yield and r^*. The term $100/\overline{E/P}$, with $\overline{E/P}$ the sample average, converts this gap to the units of the log CAPE, so that the weight on stocks is the same in every version. CAPE is a real valuation measure, so stocks do not change between the nominal and real versions. For r^* we use the New York Fed's current Laubach–Williams estimates (Holston et al., 2023). These "one-sided" estimates use only data up to each date, with the model's parameters estimated on the full sample.

The two-year yield. The two-year yield is adjusted in the same steps. With y_t^2 the nominal yield and π_t^2 two-year expected inflation (from the Cleveland Fed; Haubrich et al., 2012),

$$R_t^{\text{nominal}} = y_t^2, \qquad R_t^{\text{real}} = y_t^2 - \pi_t^2, \qquad R_t^{r^*\text{-gap}} = y_t^2 - \pi_t^2 - r_t^*. \tag{8}$$

Expected inflation and r^* are monthly or quarterly and move slowly. The daily series add their interpolated monthly values to daily market prices, so day-to-day moves come from markets (Appendix B).

2.2 Why financial conditions and r^*

[TO DO: Moved from old Section 2 (background) and old Section 5 (scope). Rewrite as the mechanism case for the FCI and the r* adjustment and how they connect to the other solutions in the literature; keep the risk-appetite material (subsubsection below, without extra tables).]

This section sets out the reasoning behind the design. We first describe how monetary policy is thought to reach spending and prices. We then show why a standard VAR can miss this route, and why that could produce the puzzles. Finally, we connect the argument to work on financial conditions and economic activity.

2.2.1 The standard transmission mechanism

Monetary policy sets the short-term interest rate today and, through its communications, shapes what people expect that rate to be in the future. Few households and businesses borrow at the policy rate. They face the rates on consumer credit, mortgages and business debt, which arbitrage links to current and expected short-term rates. The same rise in rates raises the return investors require on stocks. For businesses, a higher cost of capital raises the user cost of new equipment and buildings, and investment falls (Jorgenson, 1963; Hall and Jorgenson, 1967). The value of existing capital relative to its replacement cost falls as well (Tobin, 1969). For households, lower stock prices lower wealth, and consumption depends on wealth as well as on current income (Ando and Modigliani, 1963; Friedman, 1957). Higher rates also strengthen the dollar, which shifts spending toward imports and reduces exports (Fleming, 1962; Mundell, 1963).

Interest rates of many maturities, equity prices and the dollar therefore form the core of the transmission mechanism (Boivin et al., 2010). These links run from the early work cited above to modern models of the business cycle, in closed and open economies (Christiano et al., 2005; Smets and Wouters, 2007; Galí and Monacelli, 2005). Models with heterogeneous households give more weight to the indirect effects that work through income (Kaplan et al., 2018; Auclert, 2019). But in all of these models the short-term rate matters mainly because of what it does to the prices and rates that people actually face. And they act with a lag (Friedman, 1961).

What matters in these models is not the nominal rate but the real rate relative to the neutral rate r^*. The same holds for the other parts of financial conditions: a given yield or stock valuation is tighter when r^* is low than when it is high. The distinction matters most for inflation. Spending responds to financial conditions within months. Inflation responds to the slack that builds up over time, so it depends on how long, and by how much, conditions stay tight relative to r^*. A measure of conditions that ignores a falling r^* will overstate how tight policy has been, and by more the longer the period. That error is largest for the cumulative effects that drive inflation.

2.2.2 What standard VARs leave out

The workhorse evidence on monetary policy comes from VARs with a few macroeconomic variables and one interest rate (Bernanke and Blinder, 1992; Christiano et al., 1999). Some studies add a credit spread (Gertler and Karadi, 2015; Caldara and Herbst, 2019), and factor models bring in many more series (Bernanke et al., 2005). But long-term yields, equity valuations and the dollar are usually absent from the small models used to measure the effects of policy, although some recent work adds the dollar and stock-market volatility (Boehm et al., 2026). These are the variables that, on the mechanism above, carry those effects. Concern about missing variables is not new: Sims (1992) argued that the price puzzle arises because the Federal Reserve responds to information that small VARs do not contain (see also Castelnuovo and Surico, 2010). Our concern is different. Here the missing variables are the channel itself.

A simple model shows what this omission can do. Let U_t be the unemployment gap, i_t the policy rate and f_t financial conditions, with a higher f_t meaning tighter conditions:

$$U_t = \rho_U \, U_{t-1} + \kappa \, f_{t-1} + \varepsilon_t^U, \tag{9}$$

$$f_t = \rho_f \, f_{t-1} + \lambda \, i_t + \varepsilon_t^f. \tag{10}$$

Unemployment responds to financial conditions and not directly to the policy rate. Financial conditions respond to the policy rate and to other forces, ε_t^f, such as changes in risk appetite. Some of these other forces may themselves be policy news that does not move interest rates (Boehm and Kroner, 2024; Bauer et al., 2026). Suppose the economist observes only U_t and i_t. To remove f_t,

lag equation (9) one month, multiply it by ρ_f, subtract it from equation (9), and use equation (10). This gives

$$U_t = (\rho_U + \rho_f)\, U_{t-1} - \rho_U \rho_f\, U_{t-2} + \kappa\lambda\, i_{t-1} + \underbrace{\varepsilon_t^U - \rho_f\, \varepsilon_{t-1}^U + \kappa\, \varepsilon_{t-1}^f}_{\text{error}}. \tag{11}$$

The policy rate has no direct effect in this model. It appears in equation (11) because it stands in for financial conditions. The error is a moving average that includes past financial shocks, so a VAR in U_t and i_t with few lags cannot capture it. The VAR is misspecified. With the lags and samples available in practice, this can make the effects of monetary policy harder to measure. In some settings a policy shock may not be recoverable at all from a small set of variables (Fernández-Villaverde et al., 2007), but our argument does not depend on that.

A second problem matters more for the size and sign of the response: the omission changes the experiment being traced. In the announcement windows, the FCI used below rises about 1 unit per percentage point rise in the two-year yield. In ordinary months, its unexpected movements are only about 0.35 to 0.4 unit per percentage point. A VAR without financial conditions traces the typical move in the two-year yield, which comes with a much smaller change in financial conditions than a policy surprise does.

A small simulation shows the size of the problem. The true model is a monthly VAR in the unemployment gap, core PCE inflation, the two-year yield and the FCI, with six lags and a quadratic trend, estimated on the data of Section 2. Macroeconomic variables are ordered first. We generate 2,000 artificial samples of the same length (382 months) from this model. On each, we estimate the VAR with all four variables and again without the FCI. We then trace a policy move that raises the two-year yield 1 percentage point, with no immediate effect on unemployment or inflation. With the FCI in the VAR, the move also raises the FCI by 0.99 unit, the amount measured in the announcement windows. Without it, the same move raises only the yield. Table 1 shows the results. These VARs are monthly and simpler than the model of Section 2, so their true responses are not the estimates of Section 3.

Table 1: Simulation: estimating the effects of policy with and without financial conditions

		True	With the FCI		Without the FCI	
		response	Mean (s.d.)	Wrong sign	Mean (s.d.)	Wrong sign
Nominal	Unemployment, 12 months	+0.36	+0.32 (0.18)	4%	-0.08 (0.18)	66%
	Price level, 24 months	-0.32	-0.34 (0.25)	8%	-0.21 (0.23)	18%
r^*-gap	Unemployment, 12 months	+0.51	+0.43 (0.19)	1%	+0.11 (0.17)	26%
	Price level, 24 months	-0.84	-0.75 (0.25)	0%	-0.57 (0.22)	1%

Responses to a policy move that raises the two-year yield 1 percentage point; unemployment gap in percentage points, core PCE price level in percent. True model: monthly VAR in the unemployment gap, core PCE inflation, the two-year yield and the FCI (six lags, quadratic trend), estimated on 1994–2026, with the two-year yield and the FCI in the form shown. 2,000 samples of 382 months; estimated VARs have six lags. Mean and s.d.: across samples. "Wrong sign": share of samples in which the estimate has the opposite sign to the true response.

The VAR with the FCI comes close to the true responses. The VAR without it does not. In the nominal case, the true unemployment response after 12 months is +0.36. The VAR without the FCI gives −0.08 on average, and the estimate has the wrong sign in two-thirds of the samples. In the r^*-gap case, it gives +0.11 against a true response of +0.51. The price effects are also understated, though less severely. More data would reduce the noise but not this error: with ten times as many months, the nominal estimate is still −0.08. The simulation illustrates the mechanism and does

not prove it, because the true model is one in which financial conditions matter by construction. But it shows that if they do matter, a small VAR that omits them can produce the wrong-signed responses found in practice.

High-frequency surprises help identify the shock, but they do not by themselves fix how it is carried forward. Our design therefore does two things. It includes financial conditions in the system, so that they carry the effects of the surprise forward, as in equation (9). And it measures the immediate effect of the surprise on the two-year yield and on financial conditions directly in the announcement window, where policy news is the main force at work. The measurement of f_t also matters. If activity responds to financial conditions relative to r^*, a measure that ignores r^* differs from the true f_t by a slow-moving error, and that error enters equation (9).

2.2.3 Financial conditions and real activity

A separate literature asks how financial conditions are related to economic activity. Asset prices help forecast output and inflation, but which ones help changes over time (Stock and Watson, 2003). Credit spreads, and especially their excess bond premium component, are strong predictors of activity (Gilchrist and Zakrajšek, 2012). Broad indexes summarize many such series and are used to assess the outlook (Hatzius et al., 2010; Brave and Butters, 2011). Financial conditions are also linked to the risks around growth, not only to its average (Adrian et al., 2019), and their relationship with unemployment may be nonlinear (Kiley, 2020a). Federal Reserve staff now publish a measure of the effect of financial conditions on growth, with weights from large macroeconomic models (Ajello et al., 2023).

This work has a limit that the event-study literature does not. A correlation between financial conditions and later activity need not reflect a causal effect, because financial conditions also respond to the economy. Hatzius et al. (2010) address part of this problem by removing the effects of past growth and inflation from their indicators. The companion note uses the timing in a VAR for the same purpose (FCI note, 2026). The two literatures have complementary strengths. Work on high-frequency surprises identifies policy shocks cleanly but carries them through a small set of variables. Work on financial conditions studies a broad set of variables but does not isolate policy shocks. We bring them together: the weights in our index come from how its components respond to policy news, and the surprise is carried forward through the estimated relationship between that index and the economy.

2.2.4 Policy news beyond interest rates, and risk appetite

Policy news beyond interest rates. Recent work finds that announcements move stock prices and the dollar much more than interest-rate surprises can explain (Boehm and Kroner, 2024; Bauer et al., 2026). Appendix Table A5 checks what this means for our design. In our 252 windows, the policy-news surprise explains 80 percent of the variance of the move in the two-year yield, but only about a third for the 10-year yield (32 percent), the S&P 500 (31 percent) and the dollar (34 percent), and 48 percent for the FCI. The part of the FCI's move that the surprise does not explain is as large as the part we use: its standard deviation is 0.06 index unit, against 0.05 for the move that comes with a one-standard-deviation surprise.

The window ratio b_F is fairly stable. It ranges from 0.87 to 1.17 across 1996–2007, 2008–2019, 2020–2026 and 2020–2023, and its 90 percent intervals overlap when announcements are split by the level of the VIX or the excess bond premium. Bauer et al. (2026) find that the link between interest-rate surprises and risk appetite varies a lot with the state of markets; in our windows, the link between the surprise and the FCI varies less.

The unexplained part of the FCI's move has effects of the standard sign. We trace a one-standard-deviation move in it through our model, with no move in the two-year yield. Unemployment rises 0.03 percentage point after 12 months, and the core price level falls 0.02 to 0.03 percent after 24 months at the r^* step, both significant. These signs match those that Bauer et al. (2026) and Boehm et al. (2026) find for policy-driven shifts in risk appetite, and the sizes are similar to those of a one-standard-deviation policy surprise.

There are two readings of this unexplained part. On one, it is mostly news unrelated to policy that happens to arrive in the window, and our estimates capture the effects of policy. On the other, much of it is policy news that does not move interest rates, as Boehm and Kroner (2024) and Bauer et al. (2026) argue. Then our estimates are the effects of one dimension of policy news, and the effects of all policy news through financial conditions could be up to about twice as large. Both readings agree on the channel: policy news reaches the economy through broad financial conditions.

Credit. Credit is the most important channel we leave out of the baseline (Gilchrist and Zakrajšek, 2012; Caldara and Herbst, 2019). Appendix D adds it in two ways. Adding the daily Baa-10-year spread, and letting it respond on the announcement day, barely changes the results: at the r^* step, unemployment rises 0.28 to 0.35 percentage point after 12 months and the price level falls 0.48 to 0.65 percent after 24 months, significant for all lag lengths. Adding the monthly excess bond premium as a third monthly variable leaves the results with the FCI almost unchanged. But without the FCI, the premium removes the wrong-signed unemployment response. So credit conditions offer a partial alternative to the FCI for the unemployment puzzle, though not for the price result. One reading is that the premium, like the FCI, absorbs policy-driven moves in risk premia (Bauer et al., 2026).

The parts of the FCI. Replacing the FCI with its three weighted parts, entered separately, leaves the signs unchanged but makes the estimates less precise. The price result is then significant only with 12 lags. A test of the proportional-weights restriction does not reject it at the 5 percent level for unemployment at any step, or for either variable at the r^* step (Appendix D).

Commodity prices and output. Commodity prices mark a limit of the approach. Appendix Table A6 adds the IMF all-commodity price index. Commodity prices then rise after a tightening, by 2.7 to 7.2 percent after 24 months at the r^* step (not significant), and by more at the nominal step. This differs from Boehm et al. (2026) and Bauer et al. (2026), who find that oil and commodity prices fall after a contractionary shock. In this larger model, industrial production also rises rather than falls, and the unemployment effect is smaller (0.16 to 0.25 percentage point after 12 months at the r^* step). The price-level effect is similar (0.30 to 0.62 percent after 24 months). Our assumptions are least plausible for prices like these, which look ahead and respond strongly to demand.

2.3 Timing assumptions and identification

The shock is the Nakamura–Steinsson policy-news surprise, s_a in equation (1), from the San Francisco Fed's U.S. Monetary Policy Event-Study Database (Acosta et al., 2025). We use the 252 FOMC announcements from January 1996 to July 2026 with all the window measures available (Appendix B). The window runs from 10 minutes before the statement to 60 minutes after the press conference starts, or 30 minutes around the statement when there is no press conference. Identification comes from timing, at three frequencies. Table 2 summarizes the assumptions.

Table 2: Timing assumptions

Frequency	What can move	Assumption	Equation
Window (minutes)	Two-year yield and FCI, by the amounts measured in the window	News about the path of interest rates is the main systematic force in the window, and the only one correlated with the surprise. Unemployment and inflation do not move.	(13)
Daily	Two-year yield and FCI, each day after the announcement	They depend on their own recent history and on the unemployment and inflation of this month and last month.	(14)
Monthly	Unemployment and inflation, from the month after the announcement	Within a month, unemployment and inflation are set first. They respond to financial variables only with a lag of at least one month.	(15)

The window. The window move in the FCI is computed with the weights in equation (3):

$$\Delta F_a = w_B \, \Delta y_a^{10} + w_Q \, \Delta \mathrm{SP}_a + w_D \, \Delta \mathrm{DXY}_a. \tag{12}$$

These are the measures available within the day, and the ones used to estimate the weights. Percent changes in the S&P 500 equal percent changes in CAPE within a window, because earnings are fixed. We express all effects per percentage point on the two-year yield in the window. The effect on the FCI is the ratio of two regression slopes on the surprise, an instrumental-variables estimate with s_a as the instrument:

$$b = \begin{pmatrix} 1 \\ b_F \end{pmatrix}, \qquad b_F = \frac{\sum_a (\Delta F_a - \overline{\Delta F})\,(s_a - \bar{s})}{\sum_a (\Delta y_a^2 - \overline{\Delta y^2})\,(s_a - \bar{s})} = 0.99. \tag{13}$$

This is close to one because the weights are normalized that way. It is not exactly one because this regression includes a constant, which the scaling in equation (1) does not, and because it uses one fewer announcement. Expected inflation and r^* move slowly, so we take the window move to be the same in every version.

The day. On the announcement day, the two-year yield and the FCI shift by the vector b. We use the window move rather than the change over the whole day, because the full-day change contains other news. On later days, the two series move as equation (14) implies. They affect each other only through the daily lags, so no ordering between them is needed within the day. The window fixes their joint move.

The month. Within each month, unemployment and inflation are set first, and markets then respond to them. So in the month of the announcement, unemployment and inflation have not moved. They respond from the next month on, through the monthly average of the daily financial series. That average depends on when in the month the announcement falls: an announcement late in a month affects few days of that month's average. This is how the model takes the timing of announcements into account, as Jacobson et al. (2026) recommend. The ordering is the familiar recursive one, in which slow-moving macroeconomic variables come before financial variables (Bernanke and Blinder, 1992; Christiano et al., 1999). It also means that the daily equations include the current month's unemployment and inflation, even though those figures are published later. We treat this as a modeling convention: the monthly values summarize conditions that markets observe as the month unfolds.

The key assumptions. Two assumptions carry the results. The first is the usual one in a VAR. Once the shock has been identified, the economy responds to a change in the financial variables in the same way whatever caused it. A policy shock identified by a Cholesky ordering or an external instrument is traced through the same estimated dynamics as every other shock, and we do the same. This has a familiar cost. Stock prices partly anticipate future activity, so a move that policy news pushes through stocks need not act on the economy like a move with another cause. This is the same problem as the information effect in any VAR with a high-frequency shock; as in the companion note, we acknowledge it and set it aside.

The second assumption is specific to this paper and has two parts. A standard VAR estimates the effect of the shock on every variable in the system. Here, the surprise reaches unemployment and prices only through the two-year yield and the FCI, and has no direct effect on them in the window. Anything else it moves, such as credit spreads or expectations, is left out. So are the moves in stock prices and the dollar in the window that are unrelated to s_a; the surprise explains only about a third of those moves (Section 2.2.4). The non-yield shock of Boehm and Kroner (2024) is uncorrelated with policy-news surprises, so such moves do not bias b_F. But the weights in equation (3) treat them as noise, and part of them may be policy news (Boehm and Kroner, 2024; Bauer et al., 2026). In addition, the monthly equations see the FCI as a single index. Its weights show how the three components respond to policy news, not how the economy responds to each. So we assume that the three affect unemployment and prices in proportion to those weights. Section 2.2.4 and Appendix D relax both parts.

2.4 A mixed-frequency VAR

Structure. The model has a daily block and a monthly block. Let $x_\tau = (R_\tau, F_\tau)'$ hold the two-year yield and the FCI on day τ, in the same version. Let $m_t = (U_t, \pi_t)'$ hold the two monthly variables. The unemployment gap U_t is the unemployment rate minus the CBO estimate of its natural rate. The CBO estimate does not respond to the surprise, so the response of the gap equals that of the unemployment rate. Inflation is $\pi_t = 1200\,\Delta \ln P_t$, where P_t is the price index for personal consumption expenditures excluding food and energy (core PCE).

The daily block is a VAR in the style of the heterogeneous autoregression of Corsi (2009):

$$x_\tau = \alpha + \sum_{k\in\{1,5,22,66\}} \Phi_k\, \bar{x}^{(k)}_{\tau-1} + \Gamma_0\, m_{t(\tau)} + \Gamma_1\, m_{t(\tau)-1} + \xi_\tau, \tag{14}$$

where $\bar{x}^{(k)}_{\tau-1}$ is the average of x over the k days through $\tau-1$, and $t(\tau)$ is the month of day τ. Averages over about a day, a week, a month and a quarter capture persistence with few coefficients. When the FCI is left out, x_τ is the two-year yield alone.

The monthly block is

$$m_t = c + \sum_{l=1}^{L} A_l\, m_{t-l} + \sum_{l=1}^{L} G_l\, \bar{x}_{t-l} + \theta_1\, t + \theta_2\, t^2 + \zeta_t, \qquad \bar{x}_t = \frac{1}{n_t}\sum_{\tau\in t} x_\tau, \tag{15}$$

with n_t the number of weekdays in month t. The model is a mixed-frequency VAR (Ghysels, 2016). In the language of mixed-data sampling, the weights are equal across days within a month and unrestricted across months (Ghysels et al., 2007; Foroni et al., 2015). The equation contains no current-month term in $\bar{x}_t$, which is the timing assumption of Table 2.

Relation to a monthly VAR and a proxy VAR. Suppose the daily block were replaced by a monthly equation for $\bar{x}_t$, and every announcement occurred on the first day of the month. With $Z_t = (m_t', \bar{x}_t')'$, the model would then be a standard monthly VAR with a recursive ordering, the

macroeconomic variables first, and impact vector $(0, 0, b')'$. The daily block adds two things: the position of each announcement in its month, and fast dynamics of the financial variables, estimated on many more observations. A proxy VAR (Gertler and Karadi, 2015; Mertens and Ravn, 2013; Stock and Watson, 2018) instead estimates $Z_t = \sum_l C_l Z_{t-l} + \iota_t$ and uses as an instrument z_t the surprises summed over the month. The effect on the FCI per unit effect on the two-year yield is then

$$\frac{\mathrm{Cov}(\iota_{F,t}, z_t)}{\mathrm{Cov}(\iota_{R,t}, z_t)}. \tag{16}$$

The window ratio b_F in equation (13) has the same form, with three differences. It replaces monthly VAR residuals with changes measured inside the window, which do not depend on how strongly the surprise predicts monthly residuals. It sets the entries for unemployment and inflation to zero rather than estimating them. And it dates each shock to its day rather than summing shocks over a month. Section 3.5.2 estimates both monthly benchmarks.

The time trend. Every monthly equation includes a smooth quadratic time trend. Over 1994–2026, unemployment, inflation and interest rates contain slow movements that a short monthly model cannot capture. Rates drifted down along with r^*. Inflation was low in the 2010s and rose after 2020. The natural rate of unemployment may have shifted in ways the CBO estimate misses. Without a trend, these slow movements show up in the estimated effect of the financial variables, and trend gets mixed with transmission. A quadratic is the simplest smooth trend that allows inflation to fall and then rise. Section 3.5.1 shows that measuring rates relative to r^* does much of the trend's work.

Estimation and inference. We estimate each block by ordinary least squares. The daily block uses January 1990 to September 2026, including 2020. The monthly block uses February 1994 to September 2026, leaving out March–December 2020, which leaves 382 months. We use $L =$ 3, 6 or 12 monthly lags. Responses are computed recursively, month by month and day by day, as deviations from a path with no surprise, and averaged over the positions of the announcements within their months (Appendix B). The response of the price level after h months is $\sum_{j=0}^{h} \tilde{\pi}_j/12$. A bootstrap with 200 draws resamples the announcements, which gives new values of b and of the announcement positions, and the residuals of the monthly block. We report 90 percent intervals, as recent studies in this area do (Bauer and Swanson, 2023a; Caldara and Herbst, 2019; Miranda-Agrippino and Ricco, 2021; Ramey, 2016), and 68 percent intervals, which Jarociński and Karadi (2020) report alongside them. The FCI weights and r^* are held fixed. In large samples a VAR of this kind estimates the same effects as local projections (Plagborg-Møller and Wolf, 2021).

3 Baseline results

[TO DO: Subsections 3.1 to 3.3 are rewritten (10 Nov 2026) with generated numbers; the rest of this section (3.4 onward) still has numbers from the earlier quadratic-trend, multi-lag draft: replace them with macros from baseline/07_report.py. Order: 3.1 three steps; 3.2 perverse responses; 3.3 significant and plausible effects; 3.4 implied sacrifice ratio; 3.5 how the baseline resolves the puzzles; 3.6 a purely monthly VAR as a benchmark. Sample: monthly equations and shocks both start in 1996.]

3.1 The three steps

We report three steps. In each, the two-year yield enters alone and then together with the FCI of the same step: nominal measures; real measures, net of expected inflation; and measures relative

to r^*, net of expected inflation and of the Laubach–Williams estimate of r^* (Section 2.1 gives the definitions). Table 3 shows the responses of the unemployment gap and the core PCE price level, 12, 24 and 36 months after a policy move that raises the two-year yield 1 percentage point in the announcement window. The monthly equations have 12 lags, fixed in advance; Appendix Table A1 shows 3, 6 and 12 lags. The shocks and the monthly equations both start in January 1996, the first announcement for which all window measures are available (369 monthly observations). Figure 1 shows the impulse responses.

Table 3: Baseline: 1996 to the present, all data in, no trend (12 lags)

				Unemployment gap (pp)			Price level (%)

Nominal, real and r*-gap 2-year yield; the FCI is Note A's index in the matching form in each case. Per +1 pp on the 2-year yield. * = 90% interval excludes zero; intervals in brackets. Obs = monthly observations in the equations.

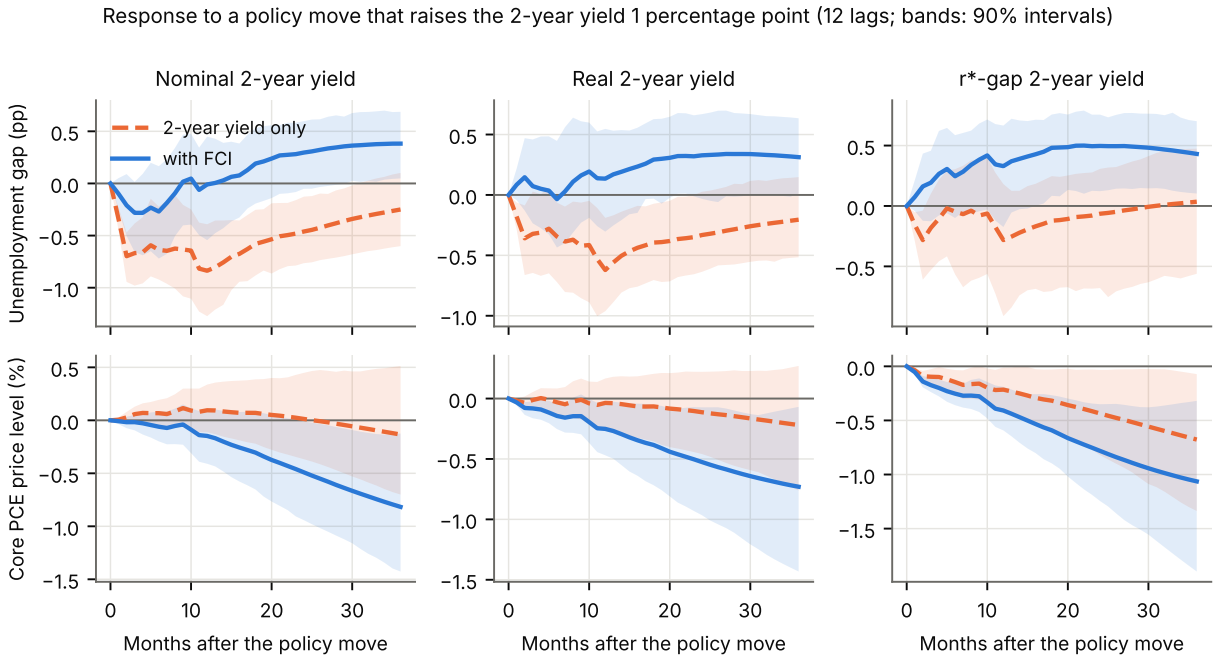

Figure 1: Responses to a policy move that raises the two-year yield 1 percentage point, without and with the FCI (12 lags). Bands: 90 percent intervals.

The two-year yield alone. At the nominal and real steps unemployment falls after a tightening, by 0.84 and 0.62 percentage point after 12 months (significant and significant), and the price level does not respond (0.01 and −0.11 percent after 24 months). Relative to r^*, the yield alone gives no rise in unemployment (−0.28 after 12 months) but does give a price fall of 0.44 percent after 24 months (significant).

With the FCI. Adding the FCI removes the fall in unemployment at every step: after 12 months the response is −0.01, 0.13 and 0.33 at the nominal, real and r^* steps, and after 24 months 0.30, 0.33 and 0.50. The price level falls at every step, by 0.49, 0.53 and 0.78 percent after 24 months and by 0.82, 0.73 and 1.06 percent after 36.

Reading across the steps. With the FCI, the price fall is significant after 24 and 36 months at every step. The unemployment rise is significant after 36 months at every step but after 24 months only at the r^* step. The r^* step gives the largest price response and the unemployment response that is significant at the most horizons; but the FCI alone already removes the fall in unemployment and produces a significant price fall.

3.2 Perverse responses

Two features of the evidence on high-frequency monetary policy surprises have been called perverse. The first is that unemployment and output do not respond in the conventional direction to a tightening. Miranda-Agrippino and Ricco (2021) find an output and unemployment puzzle with the unadjusted Gertler–Karadi instrument, which disappears when the instrument is orthogonalized to the Fed's forecasts (as replicated and discussed by Bauer and Swanson, 2023a); Bauer and Swanson (2023a) show that unadjusted surprises give small, imprecise responses, while surprises orthogonalized to public information give large ones. The second is the price puzzle of Sims (1992), a rise in prices after a tightening; Bauer and Swanson (2023a) find none in their VAR estimates when the surprises are orthogonalized.

In our data the two-year yield alone reproduces both features at the nominal and real steps: unemployment falls significantly and the price level does not respond significantly (Table 3 and Figure 1). With the FCI the responses are conventional at every step: unemployment does not fall significantly, and the price level falls significantly after 24 and 36 months. The next subsection compares the size of these responses with the literature. We do not claim that adding the FCI and measuring the stance against r^* explains the puzzles; we report that they identify specifications in which the responses are conventional. Section 3.5 asks what accounts for the change.

3.3 The size of the effects

Figure 2 starts from the standard approach, the nominal two-year yield alone (dashed line), and sets it against the baseline, the r^*-gap two-year yield with the FCI (solid line, with 68 and 90 percent bands). The dotted line adds the FCI to the nominal yield. The two approaches give different answers on both outcomes. With the nominal yield alone, unemployment falls, to −0.84 percentage point after 12 months at its lowest, and is still −0.25 after 36 months; the price level is essentially flat (within 0.15 percent of zero at every horizon in Table 3). In the baseline, unemployment rises to 0.50 percentage point after 22 months, and the price level falls steadily, by 1.06 percent after 36 months. The dotted line shows how much of the difference the FCI alone makes: unemployment is 0.38 after 36 months and the price level falls by 0.82 percent.

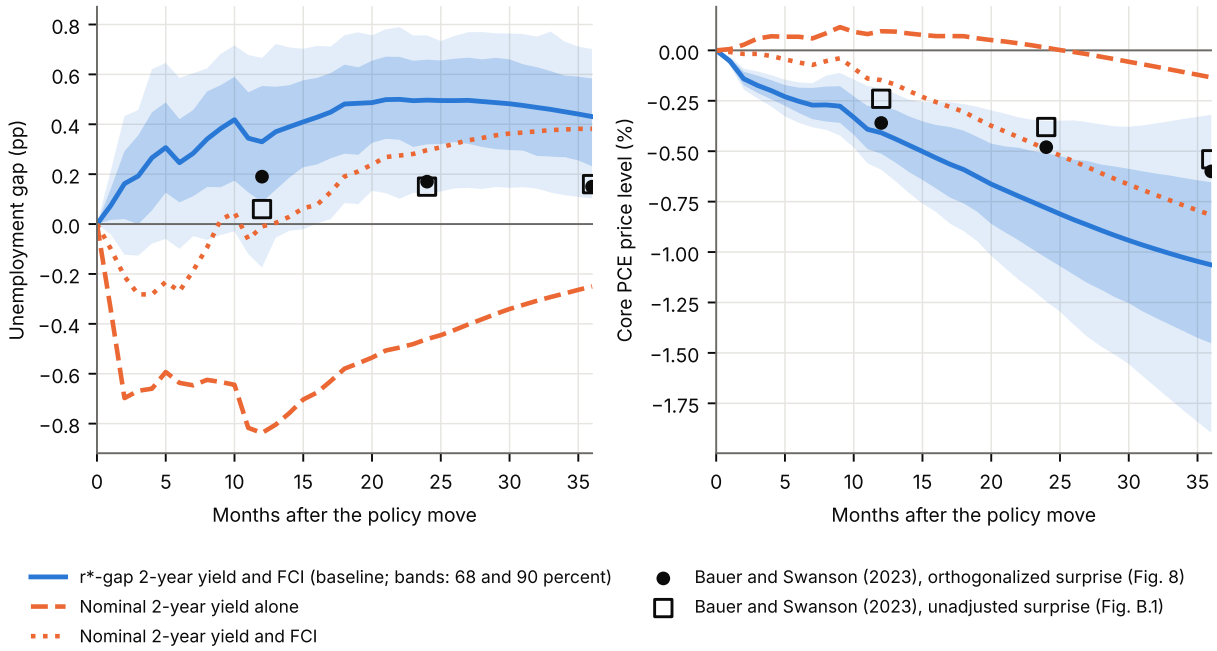

Figure 2: Responses to a policy move that raises the two-year yield 1 percentage point: the nominal two-year yield alone and with the FCI, and the baseline (r^*-gap two-year yield and FCI; 12 lags; shaded bands 68 and 90 percent). Markers: Bauer and Swanson (2023a), per 1 percentage point; values read from their Figures 8 and B.1 and multiplied by four (their shock is normalized to raise the two-year yield 25 basis points on impact; CPI rather than core PCE; VAR estimated for 1973–2020 with the end-of-month two-year yield).

These contrasts mirror the literature on the perverse responses. Bauer and Swanson (2023a) estimate structural VARs with external instruments and normalize the shock to raise the two-year yield 25 basis points on impact. Their VAR uses the end-of-month yield; in our model the two-year yield at the end of the announcement month is 0.97 (nominal) to 0.99 (r^* step) of the window move, so their normalization and ours are close, and their results can be shown on the same axes. With surprises orthogonalized to public information, their benchmark (their Figure 8; circles), unemployment rises by 0.19, 0.17 and 0.15 percentage point after 12, 24 and 36 months per 1 percentage point of the two-year yield, and CPI falls by 0.36, 0.48 and 0.60 percent. With unadjusted surprises in the same VAR (their Figure B.1; squares) unemployment first falls (−0.17 on impact), turns positive after about seven months and is 0.06, 0.15 and 0.16 after 12, 24 and 36 months, and CPI falls by 0.24, 0.38 and 0.54 percent. Miranda-Agrippino and Ricco (2021), in the replication shown in Bauer and Swanson (2023a), scale the shock to a 100 basis point rise in the one-year yield, so their responses are not comparable in size; with the unadjusted Gertler–Karadi instrument their unemployment response is negative on impact (about −0.15 percentage point) and turns positive after about nine months, whereas with orthogonalized instruments it is positive from the start. Jacobson et al. (2026) find an initially adverse (positive) response of inflation to a one-standard-deviation Nakamura–Steinsson shock when a daily price index is aggregated to monthly frequency, but at daily frequency the response is positive only for about a month, with a confidence band that covers zero, and then turns negative; their outcome is annualized inflation and the shock is scaled to unit variance, so their sizes are not comparable to ours either.

Our baseline is larger than the Bauer–Swanson benchmark, but the benchmark values lie inside our 90 percent bands at every horizon, so the difference is within our sampling uncertainty. The responses with the nominal yield alone lie below the unadjusted-surprise responses at every horizon,

and the nominal price level does not move. These are comparisons of pattern and rough size, not replications: the samples differ (1996–2026 against 1973–2020), the instruments differ (our window surprise against their monthly instrument built from announcements and Fed Chair speeches), the outcomes differ (core PCE against CPI), and the figures were read from the printed graphs of the papers (about ±0.02 percentage point per 1 percentage point).

3.4 The implied inflation-unemployment tradeoff

Do the larger effects imply a better tradeoff for policy? Larger effects on both unemployment and prices need not do so. What matters is the ratio. Following Barnichon and Mesters (2021), we define the Phillips multiplier at horizon H as

$$\mathcal{P}_H = \frac{\tilde{P}_H}{\tilde{U}_H}, \qquad \tilde{U}_H = \frac{1}{12}\sum_{h=1}^{H} \tilde{U}_h, \tag{17}$$

where $\tilde{P}_H$ is the response of the core price level after H months, in percent, and $\tilde{U}_H$ is the cumulative response of the unemployment gap, in percentage-point years. Because the price level cumulates inflation, $\mathcal{P}_H$ is the cumulative change in inflation per unit of cumulative unemployment. Its inverse, $-1/\mathcal{P}_H$, is a sacrifice ratio: the percentage-point years of unemployment needed to lower the price level 1 percent. A more negative $\mathcal{P}_H$ means a steeper Phillips curve and a better tradeoff.

$\tilde{U}_H$ can be close to zero, and then the ratio is not well defined. So we form 90 percent sets for $\mathcal{P}_H$ in the spirit of Anderson and Rubin (1949). The set contains every value $\mathcal{P}$ for which the 90 percent bootstrap interval of $\tilde{P}_H - \mathcal{P}\,\tilde{U}_H$ contains zero. Sets can then be unbounded, which shows honestly when the data cannot pin down the tradeoff. Table 4 reports $\mathcal{P}_{24}$ and $\mathcal{P}_{36}$ for each step and for several samples.

Table 4: The implied tradeoff: Phillips multiplier $\mathcal{P}_H$ (price level per percentage-point year of unemployment)

$\mathcal{P}_H$ from equation (17): core PCE price level after H months (percent) divided by the cumulative unemployment gap response (percentage-point years). Columns: horizon, then the number of monthly lags. Brackets: 90 percent sets, the values $\mathcal{P}$ for which the 90 percent bootstrap interval of $\tilde{P}_H - \mathcal{P}\tilde{U}_H$ contains zero (200 draws, grid from −6 to 3); $\pm\infty$: the set reaches the edge of the grid; —: the set covers the whole grid, so the point estimate is not informative. **: the set excludes zero. Panel C: percentile interval of the draw-by-draw difference, using draws in which both cumulative unemployment responses exceed 0.05. All versions include the quadratic trend. For comparison, Barnichon and Mesters (2021) find about −0.15 after three to four years for 1990–2008 and about −2 after three years before 1990.

Four findings stand out.

First, with the two-year yield alone, the tradeoff cannot be measured. At the nominal and real steps without the FCI, the cumulative unemployment response is small or negative, and the sets are unbounded. This is the puzzle of Section 3.1 in another form: a tightening that does not raise unemployment says nothing about the cost of lowering inflation.

Second, measuring conditions relative to r^* steepens the tradeoff, though the difference is imprecise. With the nominal FCI, the multiplier is −0.29 to −0.49 after 24 months and −0.20 to −0.36 after 36 months, and every set includes zero. With the r^*-gap FCI, it is −0.77 to −1.06 after 24 months and −0.52 to −0.84 after 36 months, and every set excludes zero. Put as a sacrifice ratio, lowering the price level 1 percent over two years costs about 0.9 to 1.3 percentage-point years of unemployment at the r^* step, against 2 to 3.5 at the nominal step. Both parts of the ratio

move in the favorable direction: after 36 months, cumulative unemployment is smaller (1.10–1.16 percentage-point years, against 1.35–1.62) and the fall in the price level is larger (0.57–0.97 percent, against 0.33–0.54). The difference between the two steps is large but imprecise: the 90 percent interval of the draw-by-draw difference includes zero (Panel C). Without the FCI, the r^*-gap two-year yield lowers prices with little rise in unemployment, so its multiplier is very large and poorly determined. That is not a Phillips-curve channel, and we do not read it as one.

Third, the steeper tradeoff comes from recent years (Panel B). In the sample that ends in 2019, the multiplier at the r^* step is between -0.16 and $+0.03$, and every set includes zero; at the nominal step it is positive. Dropping 2021 leaves it at -0.45 to -1.13 after 24 months, with sets that exclude zero for 6 and 12 lags. With the monthly equations fitted from 1973, it is about -0.9 to -1.1, close to the baseline.

Fourth, our estimates lie between earlier estimates for the periods after and before 1990. Barnichon and Mesters (2021) find about -0.15 for 1990–2008 and about -2 before 1990; both values lie outside all our 90 percent sets at the r^* step. The numbers of Bauer and Swanson (2023a) in the note to Table 3 imply, roughly, a multiplier of -1.4 to -1.7 (for the CPI). That is steeper than ours, because their unemployment effects are smaller while their price effects are similar. So measuring conditions relative to r^* restores a tradeoff of conventional size, much steeper than the flat curves found in post-1990 samples. It does not give a better tradeoff than cleaned-shock benchmarks, and it relies on 2020–22.

3.5 How the baseline resolves the puzzles

[TO DO: Wrap-up of Section 3: what the FCI does, what the r* adjustment does, the 2-year and FCI response paths.]

3.5.1 Which part does what

Table 3 can be read as a two-by-two comparison. Including the FCI is what gives a reliable unemployment response. Measuring rates relative to r^* is what gives a strong price response. Without the FCI, the r^*-gap two-year yield already gives a strong price effect, but its unemployment effect is weak and depends on the number of lags (it is significant only with 3 lags). With the nominal FCI, unemployment rises strongly but prices fall only a little. Only with both does the economy respond in the standard way on both counts. Section 4 shows that this pattern holds across ways of adjusting the two-year yield: with any of the FCIs, unemployment rises, and with the r^*-gap FCI, prices fall, however the yield is adjusted.

Measuring rates relative to r^* also does much of the work of the time trend. Without the trend, the nominal and real steps change much more than the r^* step does (Appendix Table A3). Figure 3 shows why. From the mid-1990s to 2021, the nominal two-year yield and the nominal FCI drift down, while the r^*-gap versions show no clear trend. A monthly model fitted to the nominal series has to separate this trend from the effects of policy, and the trend runs opposite to the one in activity.

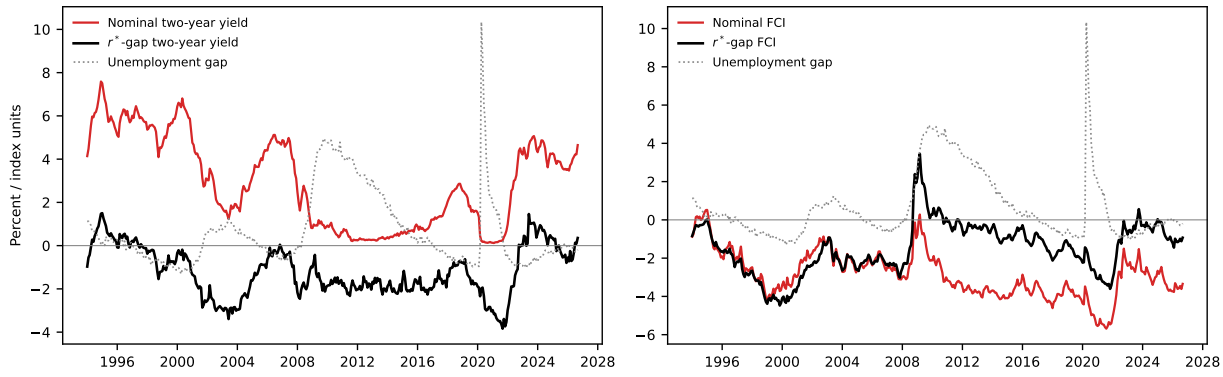

Figure 3: Nominal and r^*-gap versions of the two-year yield (left) and the FCI (right), with the unemployment gap, 1994–2026, monthly.

3.5.2 What drives the result: the window impact

How much of our result comes from the mixed-frequency model, and how much from measuring the impact in the window? To find out, we estimate a monthly VAR on the same sample, with the same trend and lags, $Z_t = (m_t', \bar{x}_t')'$, with and without the FCI, at each step. We compare four ways of setting the immediate effect of the surprise on Z_t, written S. The instrument z_t is the surprise summed over the month, and is zero in months without an announcement.

- *Standard proxy VAR.* Every element S_i is estimated as in equation (16), with variable i in the numerator.
- *Proxy with timing restrictions.* The same, but the elements for unemployment and inflation are set to zero.
- *Window impact, announcement timing.* $S = \phi\,(0, 0, b')'$, with b from equation (13). Here $\phi = 0.46$ is the average share of the month that follows the announcement.
- *Window impact, first day of the month.* $S = (0, 0, b')'$, as if every surprise occurred on the first day of the month. This gives an upper bracket on the timing.

For the proxy cases we report 90 percent Anderson–Rubin sets, which remain valid when the instrument is weak; they are conditional on the VAR coefficients. For the window cases we use the bootstrap. Appendix Table A4 gives the results.

The monthly proxy is weak. The first-stage F statistic is 4.9 to 6.3 without the FCI and 1.7 to 6.4 with it, and 5.3 to 8.3 when the funds rate and the current-meeting surprise replace the two-year yield and the policy-news surprise. Many of the sets are wide or unbounded. The proxy also implies a much smaller response of the FCI, 0.13 to 0.62 unit per percentage point on the two-year yield, than the 0.99 measured in the windows. With this estimated impact, adding the FCI does not produce a standard unemployment response: at the r^* step, the 12-month response is between −0.11 and +0.02. Other studies that use high-frequency surprises as monthly instruments report similarly weak first stages (Bauer et al., 2026), and weak instruments can bias the estimated responses (Lewis and Mertens, 2026); Boehm et al. (2026) avoid proxies for this reason.

A monthly VAR with the impact measured in the window, by contrast, gives results close to ours. With the r^*-gap two-year yield and FCI, unemployment rises 0.21 to 0.23 percentage point after 12 months with announcement timing and 0.47 to 0.51 with first-day timing, bracketing our baseline. The price level falls 0.29 to 0.39 percent after 24 months with announcement timing

and 0.62 to 0.84 with first-day timing, again bracketing the baseline. All of these are significant. Without the FCI, the unemployment response is small or has the wrong sign, whichever timing we use. The result therefore depends on two things together: including the FCI, and measuring its response to the surprise in the window. The daily block mainly refines the timing.

3.6 A purely monthly VAR as a benchmark

[TO DO: New. Standard monthly proxy VAR and window-impact versions, without and with the FCI, in the three steps, same 1996 sample and announcements (baseline/lib/monthly.py documents the equations, assumptions and references; tables tab_main_monthly and tab_monthly_F in baseline/report). Also one small simulation table (baseline table tab:proxysim, r*-gap measures only): with the model as the true process the proxy VAR is very noisy, which is all this subsection needs to show; do not add nominal/real or other simulation results. Replaces the appendix table tab:monthly and the monthly-VAR text of old Section 4.5. Cite Montiel Olea, Stock and Watson (2021) and Lunsford (2015) (verified, now in the bibliography as montiel2021, lunsford2015).]

4 Robustness

[TO DO: Core cases only (baseline/cases.py): sample (start 1973; 2020 dropped; ending 2019), the r* adjustment and trends (Kiley; real with spline), and EBP. All start in 1996, the first announcement with all window variables. Numbers in this part come from the earlier quadratic-trend, multi-lag draft; replace with the no-trend, 12-lag baseline using macros generated by baseline/07_report.py.]

4.1 The role of 2020–22

The baseline drops March–December 2020 from the months used to fit the monthly equations. But 2020 values still enter the 2021 equations as lags. Table 5 therefore also drops 2021, then ends the sample in December 2022, and separately in December 2019. In the shorter samples, the daily model is also estimated only over the shorter period.

With the r^*-gap two-year yield and FCI, the unemployment response holds up in every sample, but the price response does not. After 12 months, it is 0.26 to 0.31 percentage point when 2021 is dropped, 0.32 to 0.34 when the sample ends in 2022, and 0.42 to 0.44 when it ends in 2019. It is significant at almost every horizon and lag length. Without the FCI, its 90 percent interval includes zero in all three samples. The price effect, by contrast, depends on 2020–22. It is unchanged when the sample ends in 2022, so the data since 2023 play no special role. It stays significant with 6 and 12 lags when 2021 is dropped (-0.43 and -0.63 percent after 24 months). But in the sample that ends in 2019, the price level barely moves.

See Table 3. In the "End in" samples, the daily model is also estimated over the shorter period.

Figure 4 shows why these years are informative. After 2021, the r^*-gap two-year yield and FCI rose by about 4 percentage points, the largest swing in the stance of policy relative to r^* in the sample, and core inflation then fell. No single year drives the results. Figure 5 drops one calendar year at a time. The unemployment response after 12 months ranges from 0.26 (dropping 2021) to 0.41, and the price level after 24 months from −0.43 (dropping 2021) to −0.86. The 90 percent intervals exclude zero in every case. So the price result rests on the 2020–22 episode as a whole, a large tightening relative to r^* followed by falling inflation, not on any one year.

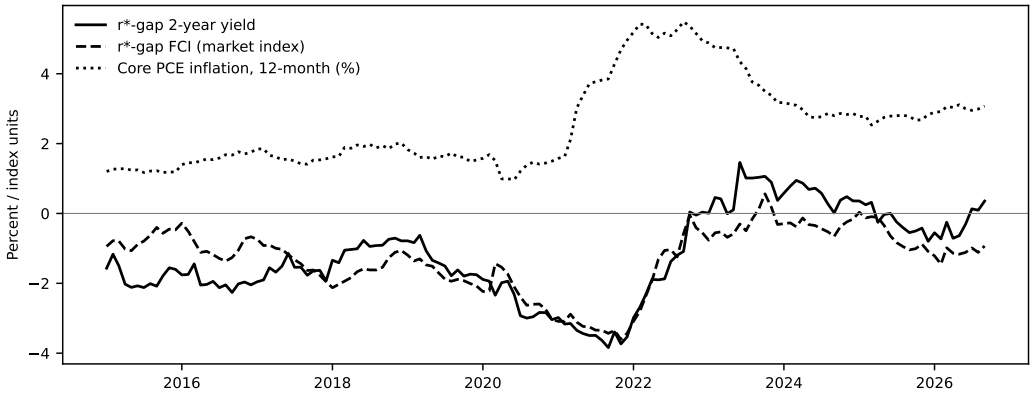

Figure 4: The r^*-gap two-year yield, the r^*-gap FCI and 12-month core PCE inflation, 2015–2026.

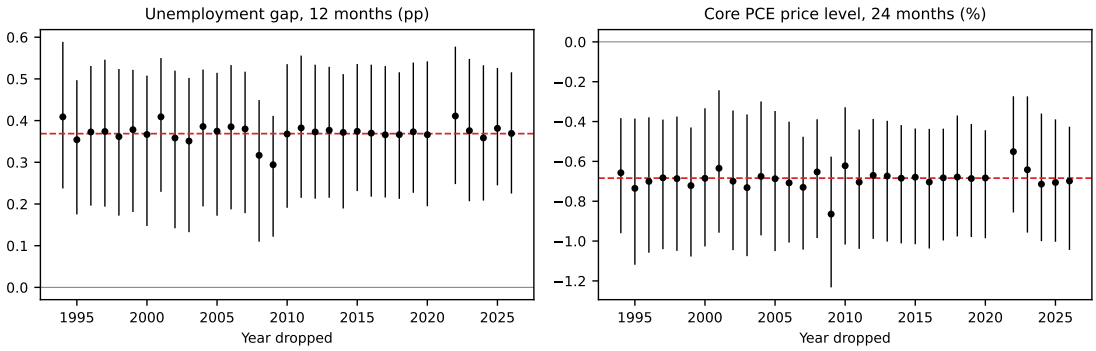

Figure 5: Dropping one year at a time. Baseline version (r^*-gap two-year yield and FCI, 6 lags; 100 bootstrap draws rather than 200, to limit computation). Each point drops one calendar year from the monthly equations. Bars: 90 percent intervals. Dashed line: full-sample estimate.

There are two readings of this dependence. On one, the episode is informative because it is the only large, sustained change in the stance of policy relative to r^* since the mid-1990s; earlier episodes were too small to move prices measurably. This reading fits evidence that the Phillips curve is steeper when the economy runs hot (Benigno and Eggertsson, 2023). On the other, the fall in inflation after 2022 partly reflects the unwinding of supply shocks (Bernanke and Blanchard, 2025) that happened to coincide with the tightening, and a linear model attributes some of it to policy. Our data cannot fully separate the two. A related concern is that r^* and expected inflation are themselves estimated partly from inflation data, which could link the r^*-gap measures mechanically to inflation in these years. We do not test these alternatives here.

4.2 The r^* adjustment and trends

[TO DO: Write from baseline Robustness 2a-d.]

4.3 Credit conditions

[TO DO: Write from baseline Robustness 3a-b (EBP).]

4.4 Earlier robustness text (to be split into the subsections above, or cut)

How should the two-year yield be adjusted? The pattern of Section 3.5.1 holds however the two-year yield is adjusted. Appendix Tables A7 and A8 keep the FCI as one of the companion note's three indexes and change only the adjustment of the yield. We try five: none; expected inflation and the Laubach–Williams r^* (baseline); expected inflation and Kiley (2020b)'s r^*; the 9–10-year forward rate from the Federal Reserve Board's estimated yield curve (Gürkaynak et al., 2007), a market-based neutral rate that replaces both adjustments; and the average of the two-year yield over the past 8 years. Without the FCI, the unemployment response is weak with a model-based r^*, and significantly negative with the nominal rate, the forward rate or the 8-year average. With any of the FCIs, it is positive at every horizon and significant in almost all cases. With the r^*-gap FCI, the price level falls 0.3 to 0.7 percent after 24 months for every adjustment of the yield, significant for every lag length. With the nominal or real FCI, the price effect is strong when the yield is adjusted with a model-based r^*, and weaker with the forward rate, which also contains a term premium that fell over the sample, or with the 8-year average. Kiley's r^* gives results close to

those with Laubach–Williams, though somewhat weaker for prices. The r^*-gap FCI always uses the Laubach–Williams r^*, so these checks do not show that the choice of r^* in the FCI is unimportant.

Other surprise measures. Appendix Table A9 replaces the Nakamura–Steinsson surprise with three others: the surprise with the part predicted by the Fed staff's Greenbook forecasts removed; the surprise of Bauer and Swanson (2023a), with the part predicted by public data removed (201 of our announcements, through 2019); and the "pure policy" surprise of Jarociński and Karadi (2020) (157 announcements). In our design, a surprise enters only through its window moves, scaled to a 1 percentage point rise in the two-year yield, and through the timing of announcements. So this check really tests how much the FCI moves per point on the two-year yield: 0.99 for the baseline, 1.07 for the Bauer–Swanson surprise and 1.09 for the Jarociński–Karadi surprise. With these ratios, the effects are slightly larger than in the baseline. At the r^* step, unemployment rises 0.40 to 0.45 percentage point after 12 months, and the price level falls 0.55 to 0.77 percent after 24 months. The Greenbook-cleaned surprise gives results within 0.02 of the baseline.

Longer samples for the monthly equations. Some studies estimate the dynamics on a longer sample and apply the surprises only to the recent period. Appendix Tables A10 and A11 start the monthly equations in 1973, 1977 or 1982; the surprises, windows and daily model are unchanged. Before the daily data exist, the model uses monthly averages, with three splices described in the table notes. The signs survive whenever the FCI is included or the yield is adjusted for r^*, but the effects are smaller.

- The unemployment puzzle depends on the 1994 start. With the nominal two-year yield alone and the 1973 start, no point estimate is negative, but the responses are small (+0.02 to +0.09 at 12 months) and mostly not significant.
- The FCI still matters for unemployment in the long samples. The response has the standard sign in every sample, horizon and lag length, and is significant at 12 months. But it is smaller: at the r^* step, 0.11 to 0.27 percentage point after 12 months with a 1973 start, against 0.36 to 0.40 in the baseline.
- A price puzzle appears with the nominal yield in the 1973 sample, though not significantly, as Castelnuovo and Surico (2010) would predict for samples that include the 1970s. Adjusting for r^* removes it. At the r^* step, with and without the FCI, the price level falls significantly at 24 months with 6 and 12 lags in every long sample, by 0.31 to 0.54 percent with the FCI.
- The signs agree across starts whenever the FCI is included or the yield is adjusted for r^*. The 1994 effects are larger by a factor of about 1.5 to 4, depending on the horizon. Industrial production falls in the 1973 and 1977 samples when the FCI is included.

These comparisons fit dynamics on different samples with the same surprises and the same window impact, and impose constant parameters within each. They are not a test of whether transmission has changed. But they give no sign that policy has become less powerful since the mid-1990s.

A fuller measure of uncertainty. Appendix Table A12 uses 1,000 draws. In each draw, it also re-estimates the daily model on randomly redrawn blocks of 66 consecutive days, and rebuilds the monthly data from the estimated model with randomly sign-flipped errors. The intervals barely change. At the r^* step, every marker of significance is the same.

Daily weights and a direct regression. To test equal weighting of days within a month, we replace $\bar{x}_t$ in equation (15) with a weighted average whose weight on the d-th weekday of a month is proportional to $1+\delta\,(2d-n_t-1)/(n_t-1)$, choose δ on a grid from -1 to 1, and test $\delta=0$. This check uses 12 lags, the nominal two-year yield, the r^*-gap FCI and no trend. The test does not reject equal weights for unemployment ($F=2.1$). It rejects them for inflation ($F=4.6$, against a 5 percent critical value of 3.9), but the gain in fit is very small: the R^2 rises from 0.435 to 0.443.

A direct regression. We also tried a method that does not need the timing assumptions: a direct regression of monthly unemployment on the daily surprises (Chudik and Georgiadis, 2022; Chudik and Kilian, 2026). With s_a the surprise on day τ_a, it estimates a daily response β_ℓ from

$$U_t = \frac{1}{n_t} \sum_{\tau \in t} \sum_{a:\, \tau_a \le \tau} \beta_{\tau - \tau_a}\, s_a + \text{error}, \tag{18}$$

with β_ℓ piecewise linear in ℓ and knots at 0, 1, 2, 3, 6, 9, 12, 18, 24, 30 and 36 months. It gives wrong-signed estimates, driven largely by the 2007–09 announcements. Its intervals are more than ten times as wide as ours, so it cannot tell our estimates apart from zero.

Other checks. Adding the Baa-Treasury spread to the daily model without any response on impact lowers the unemployment response by a third to a half. Letting it respond on the announcement day, as in Appendix D, removes most of that difference. Replacing the daily model's path for the financial variables in the first one to two months with the path estimated directly from the data gives larger but much less precise effects.

5 Conclusion and policy

[TO DO: Redo when Sections 2 to 4 are final: the policy claims (sacrifice ratio, 'FCI essential', size relative to Bauer-Swanson) wait until Section 3 is rewritten.]

5.1 Implications for policy

Policy has not lost power. Measured through broad financial conditions (longer-term yields, equity prices and the dollar), a policy move that raises the two-year yield 1 percentage point, and tightens financial conditions by about as much for a time, raises unemployment about 0.4 percentage point within a year and lowers core prices about 0.6 percent within two (Section 3.1). The unemployment effect is larger than in recent benchmarks and in a rough reading of FRB/US. The price effect is similar to the cleaned-shock benchmark for two years and larger after that. The weak or wrong-signed effects found with the nominal two-year yield alone reflect how the stance of policy was measured, not a lack of power.

Judge the stance by financial conditions relative to r^*. Policy affects the economy roughly in proportion to how much it moves broad financial conditions, and the right yardstick for those conditions is the neutral rate r^*, not zero or their past average. This supports the practice of monitoring financial conditions when setting policy, as the FOMC did in 2023 (Powell, 2023). It also explains why the same policy rate can be more or less restrictive at different times. Two cautions apply. First, r^* is uncertain, and our intervals hold it fixed. The Laubach–Williams estimates we use are one-sided, but their parameters are estimated on the full sample, so they are not what a policymaker could have known in real time. Second, with Kiley's r^*, the price effect is somewhat weaker.

The cost of disinflation. Measured relative to r^*, lowering the core price level 1 percent through tighter financial conditions costs about 1 percentage-point year of unemployment over two years (for example, unemployment half a point higher for two years). Measured in nominal terms, it would appear to cost two to three times as much, and with the two-year yield alone the cost cannot be measured at all. So part of the apparent flattening of the Phillips curve, and of the high cost of disinflation it implies, may reflect how the stance of policy has been measured. Two cautions apply. The difference between the two measures is imprecise. And it rests on 2020–22:

before 2020, our estimates show no measurable tradeoff, in line with the flat post-1990 estimates. That period may simply have lacked a tightening relative to r^* large enough to reveal one.

What this paper does not do. Our estimates are effects of surprises. They do not by themselves say how much of the 2022–24 disinflation, or of the rise in unemployment, was caused by the tightening; that requires a decomposition of the whole episode, which we leave to future work. We also do not test whether tightenings and easings, or periods of high and low inflation, have different effects.

5.2 Conclusion

Interest-rate surprises around Federal Reserve announcements measure policy shocks well, at least the part of policy news that moves interest rates. The hard part has been tracing their effects on the economy. We keep the surprise as it is and change only how its effects are traced. Two standard parts of the transmission mechanism explain much of the post-1994 puzzle: policy works through financial conditions as a whole, and what matters for spending and inflation is the level of rates and financial conditions relative to a slow-moving neutral rate. Traced this way, the effects on unemployment, prices and industrial production have the standard signs and are precisely estimated. The unemployment effect is larger than cleaned-shock benchmarks. The price effect is similar for two years and larger after that. And the implied tradeoff between inflation and unemployment is of conventional size: steeper than when conditions are measured in nominal terms, and much steeper than recent estimates of a flat Phillips curve, though not steeper than cleaned-shock benchmarks.

The two parts play different roles. Within our design, the FCI, with its response measured in the window, delivers the unemployment effect, in every version and sample we try. Measuring conditions relative to r^* delivers the price effect and the steeper tradeoff, which rest mainly on the years since 2020, when the stance of policy relative to r^* moved most.

These findings complement work on information effects, predictable surprises, timing and policy-driven risk appetite. That last line of work and ours agree that stock prices and the dollar carry much of the effect of policy. They differ in whether to treat those moves as a separate shock or as part of financial conditions. Several mechanisms can operate at once, and a natural next step is to trace cleaned or separated surprises through our approach.

Our results have limits. They rest on the assumption that the economy responds to financial conditions the same way whatever moved them, and on the time trend. Commodity prices rise after a tightening in our model. Credit conditions offer a partial alternative explanation of the unemployment puzzle. And our intervals do not include uncertainty about r^* or the FCI weights.

The broader lesson is that the fall in r^* over the past three decades is more than a fact about the level of interest rates. Unless rates are measured relative to r^*, that fall also makes the effects of policy, and the cost of lowering inflation, harder to measure.

				[−0.17, 0.67]	[0.12, 0.76]	[0.10, 0.70]	[−0.59, −0.19]	[−1.25, −0.35]	[−1.90, −0.32]

Nominal, real and r*-gap 2-year yield; the FCI is the matching index of Note A in each case. Per +1 pp on the 2-year yield. * = 90% interval excludes zero; intervals in brackets. Obs = monthly observations in the equations.

A Additional tables

Table A2: Responses with industrial production added to the monthly model

		12 months			24 months			36 months		
Step	FCI	3	6	12	3	6	12	3	6	12

	included	+0.06	+0.15	+0.28	−0.03	−0.02	−0.10	−0.13	−0.22	−0.24
C. First-stage F statistic of the monthly proxy										
Two-year yield, NS surprise	none	5.6	5.4	5.5	6.1	5.8	5.0	5.8	6.3	4.9
	included	3.1	2.5	1.7	4.1	3.4	1.7	6.4	5.9	3.2
Funds rate, MP1 surprise	none	7.7	6.5	7.3	8.0	7.5	8.3	6.4	5.8	6.5
	included	7.9	6.7	8.1	7.3	6.9	7.9	5.6	5.3	6.3

Columns: step, then the number of monthly lags. All models include the quadratic time trend. Proxy cases: per percentage point on the monthly average of the two-year yield (funds rate in the last proxy row); first-day case: the same; baseline and announcement-timing case: per percentage point on the two-year yield in the window. **: 90 percent interval or Anderson–Rubin set excludes zero. °: the 90 percent Anderson–Rubin set is unbounded. In the funds-rate rows, the funds rate receives the same adjustment as the two-year yield.

Table A5: Policy news beyond interest rates

A. Share of each window move explained by the surprise (R^2)				
2-year	10-year	S&P 500	DXY	FCI
0.80	0.32	0.31	0.34	0.48

B. Window FCI move per percentage point on the two-year yield, b_F [90 percent interval]	
VIX, lowest quartile (63 announcements)	1.12 [0.98, 1.36]
VIX, highest quartile (63 announcements)	1.01 [0.84, 1.32]
EBP, lowest quartile (63 announcements)	1.13 [0.99, 1.29]
EBP, highest quartile (63 announcements)	0.88 [0.70, 1.21]
1996–2007 (102 announcements)	0.87 [0.73, 1.08]
2008–2019 (99 announcements)	1.17 [0.95, 1.46]
2020–2026 (51 announcements)	1.07 [0.93, 1.24]
2020–2023 (30 announcements)	1.06 [0.86, 1.29]

C. Response to a one-standard-deviation window FCI move not explained by the surprise						
	Unemployment, 12 months			Price level, 24 months		
Step	3	6	12	3	6	12
Nominal	$+0.03^{**}$	$+0.03^{**}$	$+0.03^{**}$	-0.01	-0.01	-0.01
r^*-gap	$+0.03^{**}$	$+0.03^{**}$	$+0.03^{**}$	-0.02^{**}	-0.02^{**}	-0.03^{**}

252 announcements, 1996–2026. Panel A: R^2 of a regression of each window move on the policy-news surprise and a constant. Panel B: quartiles of the VIX on the previous day and the excess bond premium in the previous month; intervals from 1,000 resamples of announcements. Panel C: impact of one standard deviation (0.06 unit) of the window FCI move not explained by the surprise, with no move in the two-year yield, traced through the model with the quadratic trend; 200 draws resample announcements and monthly errors. **: 90 percent interval excludes zero; †: 68 percent only.

Table A6: Commodity prices and industrial production added to the monthly model

		Nominal			r^*-gap		
Response	FCI	3	6	12	3	6	12
Unemployment gap, 12 months	none	$+0.00$	-0.12	$-0.24^{\dagger}$	$+0.00$	-0.04	-0.08
	included	$+0.32^{**}$	$+0.23^{**}$	$+0.11$	$+0.25^{**}$	$+0.19^{**}$	$+0.16^{\dagger}$
Core PCE price level, 24 months	none	-0.16	-0.10	$+0.15$	-0.43^{**}	-0.37^{**}	-0.05
	included	$-0.20^{\dagger}$	-0.18	-0.01	-0.58^{**}	-0.62^{**}	$-0.30^{\dagger}$
Industrial production, 12 months	none	$+1.42^{**}$	$+1.61^{**}$	$+1.96^{**}$	$+0.87^{**}$	$+1.10^{**}$	$+1.09^{**}$
	included	$+0.45$	$+0.40$	$+0.76^{\dagger}$	$+0.09$	$+0.29$	$+0.46^{\dagger}$
Commodity prices, 24 months	none	$+5.36^{\dagger}$	$+6.16^{**}$	$+7.32^{**}$	$+2.44$	$+3.67^{\dagger}$	$+7.50^{**}$
	included	$+6.53^{\dagger}$	$+8.34^{**}$	$+8.84^{**}$	$+2.68$	$+2.89$	$+7.23^{\dagger}$

See Table 3. The monthly block has the unemployment gap, core PCE inflation, 100 times the log of industrial production and 100 times the log of the IMF all-commodity price index (FRED PALLFNFINDEXM). All versions include the quadratic trend.

As Table 3, but the monthly equations are fitted from the year shown; surprises (1996 on), announcement windows and the daily model (1990 on) are unchanged. Before the daily data begin, monthly averages are used. FCI: the companion note's monthly index for the step. Two-year yield: FRED before 1990, and before June 1976 the Gürkaynak–Sack–Wright fitted two-year zero-coupon yield, shifted by its average gap to the FRED yield over 1976–1989 (about 0.25 percentage point). Expected inflation: Cleveland Fed from 1982; before 1982, the companion note's one-year expectations (Livingston survey based), which is a splice. The 1977 start avoids the yield splice, and the 1982 start avoids both. The last panel drops the time trend.

As Table 3, with 1,000 draws. Each draw resamples the announcements, re-estimates the daily model on resampled 66-day blocks, and rebuilds and re-estimates the monthly data with randomly sign-flipped errors. r^* and the FCI weights are held fixed.

B Construction and estimation details

Events. We use the 252 FOMC announcements from January 1996 to July 2026 with all the window measures available in the U.S. Monetary Policy Event-Study Database (Acosta et al., 2025). As in the companion note, we leave out unscheduled announcements with no change in the policy rate, and March–April 2020. The one later announcement in the database, September 2026, is left out because too few later days are available. The DXY index used in the window covers fewer currencies than the broad dollar used in the daily and monthly index, which we treat as a measurement difference.

From monthly to daily. Expected inflation and r^* are not available daily, and they move slowly. We take the monthly gap between R_t^v in equation (8) and y_t^2, interpolate it linearly between the middles of adjacent months, and add it to the daily yield. The daily index is

$$F_\tau^v = w_B\, y_\tau^{10} + w_Q\, 100 \ln \mathrm{CAPE}_\tau + w_D\, 100 \ln \mathrm{DOL}_\tau + o_\tau^v, \tag{19}$$

where DOL_τ is the daily nominal broad dollar. The offset o_τ^v is the monthly difference between the index in equation (4) and the average of the first three terms, interpolated in the same way. It also absorbs the difference between the real and the nominal dollar. The monthly averages of the daily series are very close to the monthly measures: the root-mean-square difference is at most 0.02 unit for the FCI and 0.04 percentage point for the two-year yield. The offsets change little from day to day, so day-to-day moves in the index come from market prices. Table A13 shows the measures used at each frequency. The daily calendar has every weekday; missing values, such as on holidays, are filled from the previous observation for up to three days. Each daily equation has 13 coefficients with the FCI; each monthly equation has $3 + 4L$.

Table A13: Measures of stocks and the dollar at each frequency

Frequency	Stocks	Dollar
Window	S&P 500	DXY index
Daily	CAPE	Nominal broad dollar, plus offset
Monthly	CAPE, or earnings-yield gap to r^*	Real broad dollar

Tracing the effect of a surprise. The response is computed recursively, as a deviation from a path with no surprise. Let the announcement occur on weekday d_0 of the announcement month, and let $h = 0, 1, \ldots, 36$ count months from then. Tildes denote responses.

1. In each month, unemployment and inflation come first: $\tilde{m}_0 = 0$, and for $h \geq 1$,

$$\tilde{m}_h = \sum_{l=1}^{L} A_l \, \tilde{m}_{h-l} + \sum_{l=1}^{L} G_l \, \tilde{x}^M_{h-l}, \tag{20}$$

   with terms dated before the announcement month equal to zero, and $\tilde{x}^M_h$ the response of the monthly average of x.

2. The days of the month follow. Before day d_0, $\tilde{x}_\tau = 0$. On day d_0, $\tilde{x}_\tau = b$ from equation (13). On every later day, with $\tilde{x}^{(k)}_{\tau-1}$ the average of the responses over the k days through $\tau - 1$,

$$\tilde{x}_\tau = \sum_{k \in \{1,5,22,66\}} \Phi_k \, \tilde{x}^{(k)}_{\tau-1} + \Gamma_0 \, \tilde{m}_{h(\tau)} + \Gamma_1 \, \tilde{m}_{h(\tau)-1}, \tag{21}$$

   where $h(\tau)$ is the month of day τ, counted from the announcement month.

3. The monthly average $\tilde{x}^M_h$ then enters equation (20) for later months.

Months after the announcement month have 21 weekdays. To avoid computing a path for every date, we form six groups of announcement dates by the weekday of the month, in blocks of four days, and compute the path at each group's average day and month length. With ω_g the share of announcements in group g, the reported response is $\sum_g \omega_g \, \tilde{m}^{(g)}_h$. Because the model is linear, these responses do not depend on the constant or the trend.

Bootstrap. In each of 200 draws, we resample the 252 announcements with replacement, which gives new values b^* in equation (13) and new group shares ω^*_g. We also resample the residuals $\hat{\zeta}_t$ of equation (15) jointly across equations, add them to the fitted values, holding the regressors fixed, and re-estimate the monthly block. The daily block is held at its estimate. We compute the response for each draw and report percentile intervals. The fuller version in Table A12 also re-estimates the daily model and rebuilds the monthly data from the model. The sets for the Phillips multiplier in Table 4 use the same 200 draws, with the announcement draws shared across steps.

C Data sources

Table A14 lists the data. Series from FRED are identified by their mnemonics. Quarterly series are placed in the middle month of the quarter and interpolated linearly.

Table A14: Data sources

Series	Frequency	Source
Unemployment rate	Monthly	FRED UNRATE
Industrial production; commodity prices	Monthly	FRED INDPRO; IMF, FRED PALLFNFINDEXM
VIX	Daily	FRED VIXCLS
Natural rate of unemployment	Quarterly	CBO, FRED NROU
Core PCE price index	Monthly	FRED PCEPILFE
Two-year Treasury yield	Daily	FRED DGS2
10-year Treasury yield	Daily, monthly	FRED DGS10, GS10
Expected inflation, 2 and 10 years	Monthly	Cleveland Fed, FRED EXPINF2YR, EXPINF10YR
r^*, Laubach–Williams	Quarterly	New York Fed, one-sided estimates
CAPE	Monthly	Shiller, spliced over 1990–92 to the monthly average of daily CAPE
Daily CAPE	Daily	S&P 500 (FRED SP500; before October 2016, Dow Jones S&P 500 history, level-matched) over Shiller's 10-year earnings

D Relaxing the key assumptions

Section 2.3 describes two restrictions specific to this paper. The surprise reaches unemployment and prices only through the two-year yield and the FCI, and the three parts of the FCI act in proportion to their weights. This appendix relaxes each in turn, and then adds a monthly credit measure to the monthly block. Table A15 repeats the main steps for the first two exercises. In each exercise the daily model and the monthly equations are extended with the new variables. Everything else is as in the baseline, including the quadratic trend and 200 draws.

Adding a credit spread. The daily model and the monthly equations now include the Baa-10-year spread: Moody's Baa corporate yield minus the 10-year Treasury yield, available daily from 1986. It is a rough measure of credit conditions. Unlike the other variables in the model, it can respond to the surprise on impact. It has no 30-minute series, so its impact is the change over the announcement day regressed on the surprise, scaled to a 1 percentage point window move in the two-year yield. The impact is -0.25 percentage point. A tightening narrows this spread on the day, because corporate yields rise less than the 10-year Treasury yield. This is not the widening that a credit channel would suggest. After the announcement the spread moves little: its monthly average response stays between -0.16 and $+0.01$ percentage point over two years.

The effects of the surprise barely change (Table A15). At the r^* step, unemployment rises 0.28 to 0.35 percentage point after 12 months, compared with 0.36 to 0.40 in the baseline, and the price level falls 0.48 to 0.65 percent after 24 months, compared with 0.53 to 0.72. All are significant at the 90 percent level for every lag length. The nominal and real steps are also close to the baseline. So leaving out this spread does not drive the results. The test is limited. The spread is crude,

because it includes expected default, and the excess bond premium that purges it is available only monthly. A better measure may behave differently.

Entering the parts of the FCI separately. The FCI is replaced by its three weighted parts: the 10-year yield, equity valuation (CAPE) and the real dollar, each in the same step (nominal, real or r^*-gap) as the FCI. The parts sum to the FCI. Each enters the daily and monthly equations with its own coefficients, so their effects on unemployment and prices are no longer tied to the weights. Their impacts per 1 percentage point move in the two-year yield are 0.32, 0.39 and 0.27 index units (together 0.99, as for the FCI).

Signs and broad size agree with the baseline (Table A15), but precision falls. At the r^* step, unemployment rises 0.48, 0.33 and 0.18 percentage point after 12 months with 3, 6 and 12 lags. The first two are significant at the 90 percent level; the third is significant only at 68 percent. The price level falls 0.30 percent after 12 months with 12 lags and 0.50 percent after 24 months, significant at the 90 percent level; with 3 and 6 lags the 24-month falls are 0.24 and 0.41, significant only at the 68 percent level at 6 lags. At the nominal and real steps, unemployment is smaller and less precise at long lags, and prices barely move. The loss of precision is expected. The three parts add $2L$ coefficients to each equation, for 382 months of data.

Table A17 tests the restriction directly. The FCI model is nested in the model with the parts, so an F test applies. It does not reject for unemployment at any step (p-values 0.10 to 0.67). For inflation it is rejected at the 5 percent level at the nominal step with every lag length and at the real step with 12 lags. At the r^* step it is not rejected at 5 percent (p-values 0.08 to 0.24). The tests are plain F tests with many restrictions and no correction for serial correlation, so they are indicative. Taken together, the FCI weights, which come from the response to policy news, summarize how unemployment responds well. For inflation they are a worse summary when rates are not measured relative to r^*, which fits the main result that the r^* step matters most for prices.

Adding the monthly excess bond premium. The excess bond premium (Gilchrist and Zakrajšek, 2012) is the part of corporate bond spreads not explained by default risk. It is monthly, so it enters the monthly block as a third variable, treated like unemployment and inflation. It depends on its own lags and on lagged monthly averages of the two-year yield and the FCI. Within a month, it is set before the financial markets move, so the daily model responds to its current and lagged values. Its response to the surprise is not set to anything: as for unemployment and inflation, it is zero in the announcement window and then evolves with the model. Table A16 gives the results.

Without the FCI, the premium removes the wrong-signed unemployment response. At the nominal step, unemployment at 12 months is -0.27 with 12 lags in the baseline and $+0.17$ with the premium; at the real step it goes from -0.20 to $+0.06$. With the FCI, adding the premium changes little. At the r^* step, unemployment at 12 months is 0.39 to 0.41, compared with 0.36 to 0.40, and the price level at 24 months falls 0.52 to 0.71 percent, compared with 0.53 to 0.72. The prices result at the r^* step without the FCI is also unchanged. The premium itself barely responds to the surprise: its response is within 0.13 percentage point at 12 months in every case, and is not significant with the FCI. So the FCI and the premium are substitutes for fixing the unemployment puzzle, but the FCI does not depend on the premium. Another reading is that the premium absorbs policy-driven moves in risk appetite, as in Bauer et al. (2026). On that reading, the FCI and the premium work in a similar way: both keep moves in risk premia from being attributed to interest rates.

Table A15: Relaxing the key assumptions: credit spread added, and the FCI replaced by its three parts

		12 months			24 months			36 months
